In the simplest of cases, a fluorimeter consists of three components. These include a light source, a sample holder, and a detector. As an illustrative example, consider the apparatus Stokes used to examine quinine solutions. Sunlight served as the source, a glass tube held the solution of quinine and his eye served as the detector. It should be noted, however, that this was a special case where the fluorescence was easily visible because the excitation wavelength was in the ultraviolet and the fluorescence emission was easily visible as blue light. In most cases, a method of wavelength discrimination is employed to select both the excitation and observation wavelengths. Therefore, practically all fluorimeters will have at least five components, which include the source, two wavelength discriminators, a sample holder, and a detector (Figure 14).

While specific configurations may vary and new technology is continually incorporated in commercial instruments, the fundamental components are invariant and will be covered in this discussion. For fear of becoming dated, we have refrained from discussing specific commercial instruments and will instead introduce the basic components and list the various technologies that are commonly employed.

Figure 14 Schematic diagram of a basic fluorescence spectrophotometer.

4.2 Light Sources

There are two primary considerations when choosing a light source, the range of wavelengths it produces and the intensity at which it produces them. A source can produce a spectrum with characteristics of either a continuous or line emission. Most sources produce light with a broad continuous emission with some spectral lines superimposed, a prime example being the xenon lamp.

4.2.1 Xenon Lamp

The xenon lamp is probably the most commonly used source in fluorescence spectrophotometers. It produces a relatively continuous emission ranging from ~200 nm up to wavelengths in the infrared region, although the intensity diminishes significantly below ~270 nm. The spectrum of a xenon lamp is shown in Figure 15.

Figure 15 illustrates the wavelength dependence of the lamp intensity, which results in a distorted excitation

Figure 15 Emission spectrum of a typical xenon lamp.

spectrum. Corrections to account for this dependence will be discussed in section 4.5. Less expensive commercial instruments will often use a 150 W xenon lamp, while more expensive research grade instruments typically benefit from lamps rated from 450 to 750 W. The more powerful lamp directly affects the sensitivity of the instrument and can lead to extremely low limits of detection.

4.2.2 Mercury Lamps

Mercury lamps are typically more intense in the ultraviolet region than xenon lamps, but they only produce light at certain spectral lines. Therefore, these lamps can only be used in cases where the spectral output of the lamp is coincident with the excitation requirements of the fluorophore. Thus, mercury lamps typically find use in specialized applications, not in a general use fluorimeter. Another lamp, although not commonly employed, is the xenon–mercury lamp, which is a mercury lamp produced with amounts of xenon gas present. The ultraviolet output is greater than the xenon lamp, but the spectral output is not as smooth.

4.2.3 Lasers

Lasers are finding increased use as excitation sources in fluorescence instrumentation. While the cost of a laser is usually a significant consideration, the high power and spectral purity result in frequent use. A major drawback of a typical laser source is the limited range of wavelengths produced. Furthermore, the wavelengths produced are typically in the red or infrared region (Nd : yttrium aluminum garnet 1064 nm, Ti : sapphire 600–1000 nm). This is a region not useful for fluorescence excitation. The laser light is typically modified in the following manner. The fundamental wavelength of the laser is frequency doubled (or tripled) to produce light in the UV/VIS region. This is then used as an excitation source for a second dye laser, which will produce light of a longer wavelength possessing various degrees of tunability, depending on the laser dye that is used. Lastly, the output from the dye laser is frequency-doubled and tuned to the desired wavelength.

Even though much of the intensity is lost during the various conversions, the resulting excitation beam can offer significant advantages over conventional sources. A significant advantage of using a laser source is the fact that many lasers can operate in a pulsed mode, making them an ideal source for measurements in the time domain. Many laser systems are now routinely capable of producing pulses of a few picoseconds and some commercial systems can produce pulses as short as 100 fs. While a full discussion of laser sources is beyond the scope of this text, the reader should be aware of their potential applicability, especially since some relatively inexpensive dye and solid-state diode lasers are now becoming commercially available.

4.2.4 Flash Lamps

One of the most routinely used pulsed sources for fluorescence lifetime measurements is the flash lamp. A flash lamp consists of a lamp filled with gas and two electrodes that are used to produce an electrical discharge through the gas. Flash lamps typically produce lamp pulses of a few nanoseconds and the spectral output depends on the type of gas that is used. The most common gas used is nitrogen, although hydrogen is often used when shorter wavelengths are desired. The discharge of the electrodes is typically controlled with a thyratron tube, which discharges at a particular frequency independent of the capacitance of the lamp. This results in a flash that is very reproducible.

4.3 Wavelength Selectors

Wavelength selectors are used to selectively transmit a particular wavelength of light. The various technologies that are available can be categorized as either filters or monochromators. Filters have the ability to absorb certain wavelengths of light, but are fixed for a given filter. Monochromators have the ability to scan a region of the spectrum. Thus, monochromators must be used to obtain excitation or emission spectra. Both filters and monochromators have advantages for certain applications.

4.3.1 Filters

Optical filters are made from glass or quartz that has been produced with an amount of certain dyes that absorb certain wavelengths of light. Optical filters can be manufactured as either cut-on filters or cut-off filters. Cut-on filters absorb light up to a characteristic ''cut-on'' wavelength, above which they transmit radiation. Cut-off filters transmit light up to a certain wavelength and absorb wavelengths greater than the ''cut-off''. Figure 16 shows transmission curves for a series of filters that can be obtained from one of several manufacturers. Optical filters offer the significant advantages of high light throughput and low cost, but suffer from a lack of selectivity.

Interference filters consist of a coated dielectric material placed between two semitransparent films. Interference of the incident light will occur between the two films and only the wavelengths that interfere constructively will be transmitted through the filter. Interference filters offer the advantage of higher selectivity over optical filters, but still pass a relatively broad range of wavelengths and their transmission is poorer than that of optical filters.

Figure 16 Transmittance curves of typical glass filters. (Reproduced with permission from Schott Glass Technologies Inc. product literature.)

4.3.2 Monochromators

The primary component of a monochromator is the dispersive element. Historically, a prism was used as the dispersive element, but today gratings are exclusively used. A monochromator consists of a grating and a set of slits to control the amount of light (and bandwidth) that enters and exits the monochromator. The type of grating and the geometry of the monochromator determine the spectral resolving power and the throughput of the monochromator. Even though the efficiency is usually higher in a system using optical filters, most commercial and research instruments are equipped with monochromators as wavelength-selective devices, due to their versatility.

4.4 Detectors

Although some systems are available that use multichannel detectors, such as photodiode arrays (PDAs) and charge-coupled devices (CCDs), most fluorescence spectrophotometers use photomultiplier tubes (PMTs) for detection. PMTs offer the advantage of inherent gain, where 10^6 to 10^9 electrons may be produced for each photon. The dark current of the PMT typically determines the detection limit of a fluorimeter. The dark current is the signal that is measured in the absence of light, due to a random nonphoton-induced cascade of electrons. Since the dark current is related to temperature, the PMT is often cooled, typically resulting in much lower limits of detection.

An additional consideration is the spectral response of the PMT, which is wavelength-dependent. Many types of PMTs are manufactured that are optimized for various wavelengths. Figure 17 shows the detector response curves for two commercial PMTs.

4.5 Spectral Correction

In an ideal fluorimeter, the measured excitation spectrum would be the same as the absorption spectrum. In reality

Figure 17 Spectral sensitivity and quantum efficiency of two commercially available PMTs. (Reproduced with permission from Hamamatsu Corporation product literature.)

Figure 18 Schematic diagram of a fluorescence spectrophotometer utilizing a reference channel for spectral correction.

this is not the case, since most components of the fluorimeter are wavelength-dependent, particularly the source. The profile of the excitation spectrum will be significantly lower in the ultraviolet region, due to the decreased intensity of the xenon source. Other instrumental artifacts will also be present due to bias in the throughput of the monochromators and the spectral sensitivity of the detector. The most common type of correction that is applied uses a reference signal, as shown in Figure 18.

In this type of correction, a small fraction of the excitation beam is split prior to the sample. This light is then used to excite a fluorescent ''quantum counter''. The quantum counter is a material that produces a signal proportional to the intensity of the incident light. One of the most commonly used quantum counters is rhodamine B. A concentrated solution of rhodamine B in ethylene glycol absorbs virtually all light from 220 to 600 nm and gives a fluorescence signal that is proportional to the intensity of the excitation source. The excitation spectrum can then be recorded using a ratio of the sample PMT signal to that of the reference PMT signal, effectively correcting for the bias in the excitation source.

Schemes also exist for correcting the emission spectra, although they are less often employed. They typically are based on the measurement of a known emission source, such as a tungsten filament. The measured response can then be modified to produce the known spectrum, thus generating a correction factor that can be subsequently applied to a measured emission spectrum. It should be noted that spectral correction is typically only necessary for the determination of quantum efficiencies and overlap integrals in energy transfer studies.

4.6 Measurement of Fluorescence Lifetimes

While a complete discussion of the instrumentation involved in the measurement of fluorescence lifetime is beyond the scope of this text, we wish to present the reader with a basic overview of the two main types of experiments that are used to measure fluorescence decays. More detailed information can be found in **Fluorescence Lifetime Measurements, Applications of**.

4.6.1 Time-domain Experiments

One of the most common configurations for measurement of lifetimes involves exciting the sample with a short pulse of light and monitoring the fluorescence intensity of the sample as a function of time. If the pulse is sufficiently short (i.e. a δ-pulse) the fluorescence signal will decay exponential from a maximum value at time zero, as shown in Equation (80):

$$I(t) = I_o e^{-t/\tau} \tag{80}$$

where I_o is the fluorescence intensity at $t = 0$, and τ is the fluorescence lifetime. Measurements are typically completed in one of three configurations, each of which will be discussed briefly.

4.6.1.1 Time-correlated Single-photon Counting In the time-correlated single-photon counting technique, the sample is illuminated with a pulse of light of short duration. This ensures that a given molecule will only be excited once during the pulse. At the instant a population of molecules are excited, they will randomly begin returning to the ground state by emitting a photon, the probability of which is described by the fluorescence lifetime (see section 3.7). Figure 19 shows schematically the time-correlated single-photon counting technique.

Figure 19 Schematic diagram of basic components involved in the time-correlated single-photon counting method.

Figure 20 The pulse sampling method of collecting fluorescence decays.

When the source produces a pulse of light, the trigger detector sends a signal to start the time-to-amplitude converter (TAC). The TAC then linearly increases the voltage on a capacitor within the TAC until a ''stop'' signal is received from the sample detector. After the ''stop signal'' the voltage is measured on the capacitor, the magnitude of which correlates to the time of detection. The voltage is sent to a multi-channel analyzer, which stores the event in a histogram representing the delay time associated with the emission event. This process is repeated until a representative histogram is built up representing the time distribution of the emission events. The data can then be deconvolved (if necessary) and are typically analyzed with a least-squares treatment. Details of these procedures can be found elsewhere[22] and will not be covered in this discussion.

4.6.1.2 Pulse Sampling (Stroboscopic) Method In the pulse sampling method, the source is pulsed repetitively and the detector PMT is gated to operate for short periods of time, relative to the fluorescence lifetime. In this manner, the detector only measures fluorescence for a certain time-window during each cycle. The delay between the excitation pulse and the measurement window is varied, such that a profile showing the intensity as a function of time is collected. The process is illustrated in Figure 20.

An alternative method exists, where the PMT gain is held constant and the collection of data is gated. A sampling oscilloscope is used to measure the intensity of the PMT during very short time-windows and a multichannel analyzer is used to construct the delay curve. An advantage of this sampling technique is that much shorter sampling pulses can be measured (~30 ps).

4.6.2 Frequency-domain Experiments

In frequency-domain measurements, a steady-state source is used, but its intensity is varied in a sinusoidal manner. Since the intensity of fluorescence emission is directly related to the intensity of the source, the emission intensity will vary with the same frequency as the source. There is, however, a time lag between excitation and emission due the fluorescence lifetime. This time lag results in a phase shift (ϕ) between the oscillation of the source and the emission (Figure 21).

Figure 21 Measurement of phase-modulated fluorescence lifetime.

Additionally, the signal is demodulated (m) relative to the modulation of the excitation source. These parameters are related to the lifetime as shown in Equation (81)

$$\tan\phi = w\tau_{\mathrm{p}} \tag{81}$$

where w is the circular frequency of the modulation and τ_{p} is the phase lifetime. Additionally, the demodulation, m, is related to the lifetime as shown in Equation (82)

$$m = \left(1 + w^2\tau_{\mathrm{m}}^2\right)^{-1/2} \tag{82}$$

where τ_{m} is the demodulation lifetime. Equation (83) applies to single exponential decays.

$$\tau = \tau_{\mathrm{p}} = \tau_{\mathrm{m}} \tag{83}$$

It should be noted that more complicated treatments are needed for multiexponential decays, discussions of which can be found in several references.[23,24] See the article **Detectors, Absorption and Luminescence** for detailed discussion of instrumentation.

The use of luminescence in analytical chemistry has gained wide acceptance, due in part to the inherent sensitivity and selectivity of the technique.

Absorption and luminescence probes are molecules or ions whose spectral properties depend upon the chemical nature of the solubilizing media in the immediate vicinity of the probe molecule. Probe character is generally evidenced by the appearance of new spectral bands, shifts in the absorption or emission wavelengths, or by changes in emission intensities. Probe molecules have been used to determine solvent polarity and solvent acidity/basicity, pH, microviscosity, temperature and/or presence of specific ions/molecules. When combined with fluorescence lifetime measurements, absorption and luminescence probes can provide additional information regarding diffusion coefficients in probe excimer formation, fluidity in lipid vesicles, and rates of intermolecular collisions in quenching experiments.

1 INTRODUCTION

Spectroscopic probe techniques are becoming increasingly popular for examining the surface microenvironment of chromatographic materials, surfactant micellization/adsorption, polymer/surfactant interactions, cyclodextrin cavities and inclusion complexes, sol–gel and inorganic glass formations, microemulsions and other molecularly organized solvent media. As typical examples, Street and Acree[1] estimated the effective dielectric constant of cyclodextrin (CD) on the basis of the measured fluorescence properties of pyrene-1-carboxyaldehyde [3029-19-4]. Stahlberg and Almgren[2] showed that the fluorescence properties of pyrene (Py) [129-00-0] could be used to investigate how the polarity of chemically modified silica surfaces varied with the surrounding solvent composition. For aqueous–methanol and aqueous–acetonitrile mixtures, the author noted large differences between the organic modifier interactions with RP-2 surfaces. Methanol decreased the polarity by hydrogen-bonding to the free silanol groups on the surface, whereas acetonitrile increased the polarity by absorbing to the alkyl chains and thus forming a layer of ''more or less freely moving'' organic molecules on the surface. Helburn et al.[3] subsequently studied the polarity and heterogeneity of reversed-phase chromatographic surfaces in equilibrium with aqueous–acetonitrile and aqueous–methanol solvent mixtures. Spectroscopic measurements using 2,6-dichloro-4-(2,4,6-triphenyl-*N*-pyridino)phenolate (ET-33) [121792-58-3] and *N*,*N*-diethyl-4-nitroaniline [2216-15-1] probe molecules indicated that the stationary phase is considerably more polar than bulk alkane solutions. Residual surface silanol groups strongly influenced the chemical and solvational properties of the interphase region.

Burrell and Hurtubise[4,5] employed solid-surface fluorescence methods and benzoquinoline probe molecules to investigate chromatographic interactions of polycyclic aromatic nitrogen heterocycles (PANHs) adsorbed onto water-deactivated silica gels. PANHs exist in both neutral and protonated forms, depending upon the acidity of the surrounding microenvironment. Protonation of a PANH molecule by a surface silanol results in the loss of fluorescence emission fine structure and a redshift in the emission wavelengths. From observed benzo[*h*]quinoline [230-27-3] emission spectra the authors were able to estimate the neutral to protonated form ratios of the various silica gel–water content compositions studied. Maximum localization of benzo[*h*]quinoline occurred near 5% water on surface sites that protonated the probe molecule.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

The last three examples pertained to characterization of chromatographic stationary phases. The observed spectral response of the probe molecule was used to elucidate the chemical and physical properties of the solvated stationary phase. Spectroscopic studies have identified several hundred organic and organometallic compounds having absorption and fluorescent spectral properties that are highly sensitive to changes in solvent polarity, temperature, viscosity, solvent acidity/basicity and/or the presence of specific ions/molecules. Theoretically, any one of these compounds can serve as a spectroscopic probe molecule. From a practical standpoint, it is extremely time-consuming to fully characterize and understand a given molecule's spectral behavior. Consequently, only a relatively small number of compounds have actually been recommended as absorption and luminescence probe molecules. Reasonable efforts have been made to identify several suitable absorption probes and several suitable luminescence probes for each type of analytical application. Depending upon the sample being studied and instrumentation availability, a luminescence probe may be preferred to an absorption probe, and vice versa. A more in-depth discussion of probe methods, including the different types of measureable physical/structural parameters, can be found in a lengthy review article devoted to fluorescent probe molecules.[6]

2 ULTRAVIOLET/VISIBLE ABSORPTION SOLVENT POLARITY PROBES

Molecular interactions between a dissolved chromophore and surrounding solvent molecules often lead to noticeable changes in the chromophore's ultraviolet/visible (UV/VIS) absorption spectrum. Change in position, intensity or peak shape that occurs when a chromophore is transferred from gas phase to a solvent is referred to as solvatochromism. The most common form of solvatochromic behavior is the change in position of absorption band maxima whenever the chromophore is dissolved in different organic solvents or binary aqueous–organic mixtures having different composition. The direction of this wavelength shift generally depends upon relative magnitude of dipole moments of ground and excited states of the chromophore as shown in Figure 1.

Initially, the chromophore and surrounding solvent molecules are in the ground electronic level (S_0) and in the ground state configuration. Time averaged ground state configuration would have the dipole moments of solvational sphere solvent molecules aligned with the chromophore's dipole moment. Upon absorption of a photon, the chromophore is excited to the S_1 (or perhaps higher) electronic excited state, which is accompanied by

Figure 1 Schematic representation of solvent effects on the electronic transition of dipolar solutes. In the diagram (a) the excited state dipole moment is larger than the ground state dipole moment, $\mu^* > \mu$. In diagram (b) $\mu^* < \mu$. (Redrawn with permission from Lu and Rutan, *Anal. Chem.*, **68**, 1381–1386. Copyright (1996) American Chemical Society.)

a corresponding change in dipole moment. On the same time scale as the absorption process, there is a redistribution of electrons in solvational sphere molecules to better align with the chromophore's new dipole moment. There is insufficient time, however, for the physical reorientation of the solvational sphere molecules or for any change in solvational sphere composition. According to the Frank–Condon principle, electronic transitions are fast compared to nuclear motions and solvent molecule movements. Lack of molecular re-orientation for both absorption and emission spectral transitions leads to preferential solvation of ground or excited state, and a shift in the energy of the electronic transition. Positive solvatochromism is, by definition, a bathochromic shift (longer wavelength, lower energy) with increasing solvent polarity. Conversely, an hypochromic shift (shorter wavelength, higher energy) of absorption band with increasing solvent polarity is called negative solvatochromism.

At a more theoretical level, numerous mathematical expressions have been derived during the past 40 years

that relate the frequency of the absorption band maxima, ν_{max}, to the refractive index, n, and the dielectric constant, ε, of the solubilizing medium. Two examples of such treatments are the Bekarek and Bayliss models which are given by Equations (1) and (2), respectively.

$$\nu_{max} = A + \frac{n^2 - 1}{n^2} \quad \frac{\varepsilon - 1}{\varepsilon} \quad C \tag{1}$$

$$\nu_{max} = A + \left\{ n^2 - \frac{n^2 - 1}{2n^2 + 1} \right\} C \tag{2}$$

In real terms A is related to the position of the absorption maxima in the gas phase spectrum, and C incorporates several solute properties and physical constants. Intermolecular solute–solvent interactions are highly complicated in nature, and extremely difficult to understand. To date, no one single theoretical treatment satisfactorily explains the observed solvatochromic behavior that results whenever different chromophores are dissolved in various microenvironments.

Lack of a single, comprehensive theoretical expression for predicting solvatochromic wavelength shifts, combined with the inadequacy of defining solute–solvent interactions in terms of simple functions of solvent properties, led to the development of solvent polarity scales deduced from the spectral behavior of select chromophores. One of the most widely used empirical scales of solvent polarities is the $E_T(30)$ scale based upon Equation (3):

$$E_T(30)\ (\text{in kcal mol}^{-1}) = \frac{28\,591}{\lambda_{max}\ (\text{in nm})} \tag{3}$$

the charge-transfer absorption of the zwitterionic 2,6-diphenyl-4-(2,4,6-triphenyl-*N*-pyridinio)phenolate molecule (ET-30) [10081-39-7].[7,8] The zwitterionic compound, also known as the Dimroth and Reichardt's betaine, exhibits one of the larger observed solvatochromic effects of any known organic molecule. Wavelength shifts amount to several hundred nanometers in going from a very polar solvent ($\lambda_{max} \approx 453$ nm in water) to a nonpolar solvent ($\lambda_{max} \approx 925$ nm in hexane). In fact, the apparent color of solutions containing the ET-30 absorption probe molecule serves as a rough indicator of solvent polarity. Methanolic solutions of the dye molecule appear wine red ($\lambda_{max} \approx 515$ nm), whereas the apparent color changes to deep blue ($\lambda_{max} \approx 622$ nm) when the dye is dissolved in acetonitrile. Numerical values of the $E_T(30)$ solvent polarity parameter are calculated from the wavelengths of maximum absorbance using Equation (3). Similarly, the $E_T(33)$ scale is defined in terms of the spectral properties of the ET-33 molecule.

Other examples of spectroscopically deduced polarity measures are the Z and Z' scales suggested by Kosower.[9] These two scales are defined by Equation (4):

$$Z(\text{or } Z') = \frac{28\,591}{\lambda_{max}\ (\text{in nm})} \tag{4}$$

the charge-transfer absorption band of *N*-ethyl-4-(methoxycarbonyl)pyridinium iodide [1199-65-1] and 4-cyano-1-ethylpyridinium iodide [1622-95-3]. Practical applications of the Z scale are limited, however, to organic solvents and aqueous–organic mixtures having low water content. The position of the charge-transfer absorption peak becomes progressively more difficult to accurately evaluate in solvent mixtures with increasing water compositions. The charge-transfer peak begins to overlap with the pyridine ring absorption. *N*-Ethyl-4-methoxycarbonyl)pyridinium iodide is thus not a suitable spectroscopic probe molecule for characterizing the aqueous–organic mobile phase commonly used in reverse-phase high-performance liquid chromatography (HPLC).

The $E_T(30)$, $E_T(33)$, Z and Z' scales are known as single parameter scales in that the solvent is described with only a single experimentally determined parameter. Multiparameter approaches exist for expressing solvent polarity effects in terms of separate contributions from polarizability, and hydrogen-bond donor and acceptor interactions. For example, Kamlet, Taft and coworkers[10,11] introduced the π^* scale of solvent dipolarity/polarizability for representing solute–solvent interactions in the absence of strong forces such as hydrogen-bonding or ion–dipole interactions. Numerical values of π^* are calculated using the $\pi \rightarrow \pi^*$ absorption band of a series of solutes, such as 4-ethylnitrobenzene [100-12-9] or *N*,*N*-diethyl-4-nitroaniline. Table 1 lists several spectroscopic probes that have been recommended for π^* determinations, along with their corresponding mathematical equations. The α- and β- scales of hydrogen-bond acceptor and donor interactions have also been derived from solvatochromic measurements. A more complete list of UV/VIS absorption spectroscopic probes and solvent polarity scales is published elsewhere.[7,8]

Solvent polarity probes have been used in analytical chemistry to characterize chromatographic stationary and mobile phases, and to describe how solute retention times vary with organic modifier composition in the case of aqueous–organic mobile phase mixtures. Johnson et al.[13] reported that plots of logarithm of capacity factor, $\log k'_{solute}$, versus $E_T(30)$ parameter were better descriptors of solute retention in binary aqueous–acetonitrile and aqueous–methanol mobile phases than were $\log k'_{solute}$ versus percent organic modifier graphs. The authors' data analysis was summarized in the form of a frequency histogram of the squared linear correlation coefficient, r^2. The histogram for the $E_T(30)$ correlations encompasses approximately 98.2% of the

332 data sets considered for $r^2 \geq 0.95$. Only 89.2% of the data sets are contained in the percent organic modifier histogram.

Carr and coworkers[14,15] applied the solvatochromic comparison method and linear solvation energy relationships in determining what solute chemical and physical characteristics govern retention in reversed-phase HPLC. The logarithm of the solute capacity factor was expressed as Equation (5):

$$\log k'_{solute} = \text{intercept} + M(\delta_s^2 - \delta_m^2)\frac{V_{solute}}{100} + S(\pi_s^* - \pi_m^*)\pi_{solute}^* + A(\beta_s - \beta_m)\alpha_{solute} + B(\alpha_s - \alpha_m)\beta_{solute} \quad (5)$$

where V_{solute} denotes that the molar volume of the solute, δ is the Scatchard–Hildebrand solubility parameter, π^* represents the polarizability/dipolarity parameter, and α and β refer to the hydrogen-bond acidity and basicity values. Each solute property is multiplied by a term that represents the difference in the complementary ''solvent'' properties for the mobile (m subscript) and stationary (s subscript) phases. The intercept and four curve-fit coefficients (M, S, A and B) are obtained through a multilinear least-squares regressional analysis. Numerical values of the coefficients determine which of the possible molecular interactions control solute retention. The more important contributions have the larger numerical coefficients. In the case of chromatographic retention behavior of a series of aromatic solutes in reversed-phase HPLC with a binary aqueous–acetonitrile mobile phase, Carr and coworkers found that solute size and hydrogen-bond basicity were the principle factors controlling retention. Multilinear correlations between pH and spectroscopically deduced solvent polarity parameters have been suggested for the standardization of potentiometric pH sensors in mixed aqueous–organic solvents.[16]

UV/VIS absorption probes have also been used to examine preferential solvation that occurs whenever a solute molecule is dissolved in a binary solvent mixture. Preferential solvation arises whenever the proportion of molecules of a given solvent component within the probe's solvational sphere is not equal to its bulk mole fraction composition. ''True preferential solvation'' is extremely difficult to theoretically model, and most published

approaches have assumed an idealized set of conditions in which the measured spectral response in the binary solvent mixture, $R_{\text{solute, AB}}$, is given by Equation (6):

$$R_{\text{solute,AB}} = X_A R_{\text{solute,A}} + X_B R_{\text{solute,B}} \quad (6)$$

a weighted mole fraction average of the probe's spectral response in the two neat solvents, $R_{\text{solute,A}}$ and $R_{\text{solute,B}}$. For UV/VIS absorption solvent polarity probes the spectral response is the reciprocal of the maximum absorbance wavelength, $1/\lambda_{max}$, and X_A and X_B refer to the mole fraction compositions of solvents A and B in the solvational sphere. Phillips and Brennecke[17] used Equation (6) to estimate the degree of preferential solvation around the solvatochromic probe phenol blue [2150-58-5]. Solvent mixtures investigated included acetone–cyclohexane, triethylamine–cyclohexane, ethyl butyrate–cyclohexane, cyclohexanone–cyclohexane, acetophenone–cyclohexane and acetophenone–toluene. In most cases spectroscopically obtained local compositions compared reasonably well with values calculated from thermodynamic models and measured solubility data. More sophisticated preferential solvation treatments take into account molecular size disparity and incorporate molar absorptivities for the different assumed solvational species.

3 ABSORPTION AND LUMINESCENT SPECIFIC ION AND MOLECULAR RECOGNITION PROBES

The idea of chemically modifying ionic or molecular analytes through complexation and/or derivatization in order to make the species more amenable to a particular spectroscopic analysis is not new. Over the past 50 years several hundred chelating ligands have been developed for the spectrophotometrical analysis of metal ions, and numerous derivatizing agents synthesized for spectrophotometric detection in conjunction with liquid chromatography and fluorescence microscopy. Probes have even been designed for select classes of biological molecules. For purposes of this review, such chelating agents and derivatizing agents are classified under the broad umbrella of absorption and fluorescent specific ion and molecular recognition probes.

Most chelating and derivatizing agents possess a chromophoric and/or fluorophoric moiety, which usually is an aromatic moiety. Such probes achieve their recognition specificity for the desired analyte either through selective complexation or chemical reaction. In the case of complexation, the ability of the probe to form molecular complex(es) is governed by the value of the formation equilibrium constant, which may depend upon analyte-probe molecular size/shape compatibility (i.e. crown ethers and cryptads). Derivatizing agents, on the other hand, achieve their selectivity through highly specific chemical reactions that occur between given functional groups on the analyte and probe molecule. A derivatizing agent thus reacts only with those molecules present in the mixture that contain the given functional group. Table 2 lists several of the common derivatizing agents that are used in HPLC to achieve enhanced absorption and fluorescence detection.

Absorption and luminescent recognition probes are often used in the construction of fiber-optic sensors for remote chemical detection. In the simplest version, the probe molecule is immobilized at the tip of an optical fiber. Light is transmitted from the radiation source to the sample through the fiber. The reflected radiation enters a second optical fiber and enables the changes in the spectral properties of the immobilized probe molecule in contact with the analyte solution to be recorded. The analyte concentration is calculated from the measured absorbance and/or fluorescent emission intensity. Specific ions that have been detected with fiber-optic chemical sensors include Cl^-, Br^- and I^- based upon fluorescence quenching of glass-immobilized quinoline [91-22-5], Be^{2+} and Al^{3+} using the immobilized fluorescent morin [480-16-0], and alkali metal ions using complexation-induced spectral changes of fluorescent crown ethers in poly(vinyl chloride) films.[21] Extensive compilations of complexing agents for the different metal ions can be found in published monographs[22–24] devoted to the subject.

Chemical sensors are also able to monitor the concentration levels of ammonia, carbon dioxide, oxygen, hydrogen cyanide and several other gaseous molecules. Chromophores employed in the absorbance-based NH_3 sensors include the acid–base indicators chlorophenol red [4430-20-0], bromocresol purple [115-40-2], bromocresol green [62625-32-5], bromothymol blue [76-59-5] and bromophenol blue [115-39-9]. Fluorescence intensity-based NH_3 sensors have contained acridine orange [10127-02-3], carboxy-4′,5′-dimethylfluorescein, 2,7-bis(2-carboxyethyl)-5-carboxyfluorescein [85138-49-4] and 8-hydroxypyrene-1,3,6-trisulfonic acid [27828-00-3] as probe molecules.[25] Similarly, cresol red [1733-12-6], phenol red [143-74-8], neutral red [553-24-2], bromothymol blue, brilliant yellow [3051-11-4], *m*-cresol purple [2303-01-7] and 3-nitrophenol [554-84-7] are used in CO_2 chemical sensors. The measured absorbance of the acid–base indicator is related to the CO_2 concentration in the sample.[26] Probes utilized in the NH_3 and CO_2 sensors actually respond to hydrogen ion, which is related to the analyte concentration through acid–base equilibria.

For example, in a typical ammonia gas sensor, the ammonia reacts with an acidic pH indicator according to

Table 2 Derivatizing agents[a] for enhanced absorption and fluorescence detection

Analyte	Derivatizing reagent	Detection
Enhanced UV/VIS absorption detection:		
Alcohols	Benzoyl chloride	UV
	p-Nitrobenzoyl chloride	UV
	p-Methoxybenzoyl chloride	UV
	3,5-Dinitrobenzoyl chloride	UV
Aldehydes and ketones	2,4-Dinitrophenylhydrazine	VIS
Amines	1-Fluoro-2,4-dinitrobenzene	UV
	Benzoyl chloride	UV
	p-Nitrobenzoyl chloride	UV
	p-Toluenesulfonyl chloride	UV
Amino acids	Phenylisothiocyanate	UV
Carboxylic acids	Phenacyl bromide	UV
	Benzyl bromide	UV
	O-4-Nitrobenzyl-*N*,*N*-diisopropylisourea	UV
	Aryl tolytriazines	UV
	2-Nitrophenylhydrazine hydrochloride	UV/VIS
Isocyanate monomers	4-Nitrobenzyl-*N*-propylamine	UV
Sugars	Phenyl isocyanate	UV
Enhanced fluorescence detection:		
Aldehydes and ketones	5,5-Dimethyl-1,3-cyclohexanedione	
	1,3-Cyclohexanedione	
	1-Dimethylaminonaphthalene-5-sulfonyl hydrazine	
1,2-, 1,3- and 1,4-Alkanediols	Phenanthrene boronic acid	
Amines	Dansyl chloride	
	o-Phthalaldehyde	
	NBD-Chloride	
	NBD-Fluoride	
	Sodium naphthoquinone sulfate	
	2-Methoxy-2,4-diphenyl-3(2*H*)furanone	
Tertiary amines	2-Naphthyl chloroformate	
Amino acids	Dansyl chloride	
	o-Phthalaldehyde	
Carboxylic acids	1-Bromoacetylpyrene	
	4-Bromomethyl-7-methoxycoumarin	
	9-(Chloromethyl)anthracene	
Sugars	Dansyl hydrazine	
Thiols	Dansylaziridine	
	N-Substituted maleimides	
	Halogenosulfonylbenzofurazans

the reaction in Equation (7):

$$HIn + NH_3 \rightleftharpoons In^- + NH_4^+ \quad (7)$$

The unprotonated form of the indicator is detected by either a fluorescence or an absorbance measurement. In the latter case, the measured absorbance, A, is related to the ammonia concentration in the sample solution by Equation (8):

$$A = \frac{\varepsilon b K_{eq} C_{In} [NH_3]_{sample}}{C_{NH_3} + K_{eq} [NH_3]_{sample}} \quad (8)$$

where ε denotes the chromophore's molar absorptivity, b is the effective pathlength at the tip of the fiber optic probe, K_{eq} represents the conditional equilibrium constant for proton transfer, $[NH_3]_{sample}$ is the ammonia concentration in the sample, and C_{In} and C_{NH_3} refer to the stoichiometric molar concentrations of the indicator and ammonia, respectively. Inspection of Equation (8) reveals that a nearly linear response occurs at low ammonia concentrations whenever $C_{NH_3} \gg K_{eq}\ [NH_3]_{sample}$. The calibration curve is linearized as a double reciprocal $1/A$ versus $1/[NH_3]_{sample}$. A similar expression holds in the case of a fluorescent probe molecule. Chemical sensors

for NH_3 and CO_2 with suitable modification permit measurement of pH directly.

Molecular oxygen can be conveniently detected with fluorosensors that rely on dynamic quenching of suitable probe molecules such as 1-pyrenebutyric acid [3443-45-6], perylene dibutyrate [79869-59-3] and 7-aminocoumarin dyes.[21] Immobilized room temperature luminescent metal chelates, such as aluminum(III) 8-hydroxy-7-iodo-5-quinolinesulfonate, zirconium(IV) 8-hydroxy-7-iodo-5-quinolinesulfonate, platinum dimer tetrakis(pyrophosphito)diplatinate(II) and $Ru(II)L_3^{2+}$ (L = 2, 2′-bipyridine, 1,10-phenanthroline and substituted derivatives) are also suitable probes for molecular oxygen sensors.[27–29] In the latter set of applications reduction in measured fluorescent and/or phosphorescent signals is mathematically related to molecular oxygen concentration, C_{oxygen}, through Stern–Volmer quenching Equation (9):

$$\frac{F_0}{F-1} = K_{oxygen}C_{oxygen} \tag{9}$$

where F_0 and F are the observed fluorescence intensity in the absence and presence of oxygen, respectively, and K is the quenching constant. Two-site Stern–Volmer models may be required at times to explain the quenching behavior of fluorophores immobilized in polymeric matrices. Microheterogeneity can cause the different solubilization sites to be quenched differently.

The newer chemical sensors are designed using fluorescent lifetime techniques. Analyte concentration is computed from the decay time of the fluorophore in contact with the sample being monitored. Lifetime-based chemical sensing is preferred over conventional intensity-based fluorescence methods because the measured lifetime is nearly independent of probe concentration. Lifetime measurements are thus unaffected by photobleaching or washout of the probe molecule. Probe molecules typically display lifetimes in the 1 to 10 nanosecond range. Molecular oxygen and ammonia have been detected based upon the spectral properties of select metal–ferron[27] and the sulforhodamine 101 [123333-78-8] + bromocresol green mixed probe resonance energy transfer system,[25] respectively. The preceding examples represent only a small fraction of the absorption and fluorescent probe-based chemical sensors that have been designed over the past two decades.

4 ULTRAVIOLET/VISIBLE ABSORPTION AND FLUORESCENT pH PROBES

Chemical sensors have been developed for pH determinations based upon both absorbance and fluorescence measurements. Probe molecules employed in the absorbance-based sensors include common acid–base indicators such as neutral red, cresol red, phenol red, bromothymol blue, brilliant yellow, bromocresol green, bromocresol purple, chlorophenol red and bromophenol blue. Extensive tabulations of acid–base indicators, and their spectroscopically determined equilibrium dissociation constants, K_{HIn}, have been published elsewhere.[30] Dissociation of indicator results in a significant wavelength shift in the maximum absorption band, which is generally accompanied by a visual change in indicator color. Protonated and unprotonated forms of the indicator have different colors. Mathematically, the hydrogen ion concentration is related to the molar concentrations of acid (HIn) and base (In^-) forms of the indicator probe molecule through the Henderson–Hasselbach Equation (10):

$$pH = pK'_{HIn} - \log\left\{\frac{[HIn]}{[In^-]}\right\} \tag{10}$$

where pK'_{HIn} refers to negative logarithm of the probe's apparent acid dissociation constant. For convenience, activity coefficients have been incorporated in the dissociation constant. Measurements are performed at fixed probe concentration, and over a narrow interval of 1–2 pH units near $pH \approx pK'_{HIn}$ a linear relationship between measured absorbance and solution pH is observed.

Mixed absorption probe systems have been used to extend the linear calibration curves by several pH units. Generally the indicator probes have approximately the same salt and same acid absorption spectrum (i.e. comparable wavelengths of maximum absorbance and nearly identical molar absorptivity ratios at the two wavelengths) with slightly different pK_a values. Concentrations are adjusted such that all probe molecules have the same measured absorbance in its salt (or acid) form at the analysis wavelength. Published studies have demonstrated that a linear absorbance versus pH calibration curve results whenever the differences in pK_as between each successive pair of absorption pH probes is 1.6 pH units. The calibration curve for a mixed probe system is more linear and extends over a considerably larger range of hydrogen ion concentrations than does the corresponding curve for single probe systems. For example, the measured absorbance is reported to be linear from pH = 1.0 to pH = 7.0 for the mixed probe system containing 25.4 mg of neutral red + 10.2 mg of methyl red + 7.8 mg of methyl yellow + 14.1 mg of thymol blue. A second four probe system, with orange IV replacing thymol blue, exhibits a linear response up to pH = 8.[31]

Fluorescence measurements also provide a convenient experimental means for pH determinations. In many applications involving chemical sensors, fluorescence-based measurements will be preferred to absorbance-based measurements because of their increased sensitivity,

greater latitude in geometric design, decreased background corrections, wider dynamic ranges, greater specificity through combined excitation–emission wavelength selection, and linear response at much lower spectroscopic probe concentrations. Generally, fluorescent pH probes are stronger acids in the excited state than in the ground state. For many pH probes fluorescence originates only from the excited state of the base form, and is observed at approximately 4–5 pH units below the ground-state pK_a. A few indicators, such as 8-hydroxypyrene-1,3,6-trisulfonic acid, are fluorescent in both basic and acidic forms. Solution pH can be monitored using hydroxypyrenetrisulfonic acid probe by simply measuring relative intensities of the molecule's basic and acidic forms, rather than by measuring the absolute intensity of the basic (or acidic) form. The calculated F_{base}/F_{acid} intensity ratio provides an internal reference point, which eliminates the necessity for repeated calibrations.

Figure 2 depicts the variation in the observed emission intensity ratios of CF, DiMCF, BCECF and HMCo as a function of solution pH. Fluorescence is measured at a fixed emission wavelength. Different excitation wavelengths are needed to excite the protonated (i.e. $\lambda_{ex} = 334$ nm in HMCo) and anionic (i.e. $\lambda_{ex} = 365$ nm in HMCo) forms of the four pH probes.[32] In the

Figure 2 Titration curves in vitro of the fluorescence ratio versus pH for 10^{-7} molar 7-hydroxy-4-methylcoumarin (HMCo), , carboxyfluorescein (CF), ■, dimethylcarboxyfluorescein (DiMCF), ∗ and biscarboxyethylcarboxyfluorescein (BCECF), ●. (Redrawn with permission from M.L. Graber, D.C. DiLillo, B.D. Friedman, E. Pasotriza-Munoz, *Anal. Biochem.*, **156**, 202–212. Copyright (1986) Academic Press, Inc.)

case of fluorescein derivatives the emission spectrum is dominated by the dianion, with only small contributions from monoanion (protonated phenol group). Both the phenol and carboxylic acid function groups of fluorescein are almost totally ionized in aqueous solutions above a pH of 9. Near linear calculated F_{base}/F_{acid} versus pH calibration curves enable a fairly accurate determination of the hydrogen ion concentration over a 1–2 unit range of pH. Sensitivity of the analytical method is determined by difference between the quantum yields of fluorescent probe's acid and base forms. For many of the recently published fluorescence methods, estimated uncertainty was reported to be ±0.01–0.1 pH units. Table 3 lists several of the common fluorescent pH probes, along with their applicable pH range and select spectral properties. The pH ranges that are given pertain to steady-state fluorescence measurements.

Three mixed indicator systems, containing both a pH-sensitive absorption probe and pH-sensitive fluorescent probe molecule, are also included in the tabulation. These particular systems were designed to provide greater sensitivity by compressing the entire observed spectral change into a much narrower range of hydrogen ion concentrations. The method is based upon primary and secondary inner-filtering effects. In a typical application, the fluorescent probe molecule would have low absorption at its excitation wavelength in acidic solutions. A weak fluorescent signal would be observed at low pH. An absorption probe molecule is added to the solution to overlap the fluorescent probe's excitation spectrum. If necessary, a second absorption probe could be introduced to overlap with the emission spectrum as well. At low pH, the absorption probe has a high molar absorptivity. At the higher pHs, the fluorescent probe has a high absorption, whereas the absorption indicator is nearly optically transparent at both the excitation and emission wavelengths. Under these circumstances, the fluorescent probe's emission signal is significantly reduced in solutions of low pH because of strong absorption of the incoming excitation radiation by the second indicator. Very slight reduction in emission signal occurs at the upper end of the pH range. The net effect of the added absorption indicator is to compress the entire observed fluorescence emission change into a much narrower range of hydrogen ion concentrations, thereby increasing the analytical method's sensitivity.[35]

SNARF and SNAFL derivatives have been used as probe molecules in fluorescent lifetime-based pH determinations. Sensors containing the probes have employed phase-modulation fluorometry. Measured phase and modulation values depend upon both the excitation and emission wavelengths, as well as the hydrogen ion concentration. Through judicious wavelength selection, Szmacinski and Lakowicz[38] demonstrated that a given

Table 3 Representative fluorescent pH probes[a] and their spectral properties

Probe/property	Probe/property
Single indicator systems:	HMCo
8-Hydroxypyrene-1,3,6-trisulfonic acid	pH range: 7.0–8.0[24]

SNARF, seminaphthorhodafluor; SNAFL, seminaphthofluorescein.

probe's useful pH range could be shifted by several pH units. The pH-sensitive range of carboxy SNARF-6 excited at $\lambda_{ex} = 543$ nm is from pH $\approx$ 5 to pH $\approx$ 10.5. Emission wavelengths of $\lambda_{em} = 660$ nm (pH $\approx$ 5–7.5) and $\lambda_{em} = 580$ nm (pH $\approx$ 7–10.5) are needed to cover the entire pH range. The wide pH range is possible because of the large wavelength shift in the emission spectra of the acid and base forms of carboxy SNARF-6.

5 FLUORESCENT WAVELENGTH-SHIFT SOLVENT POLARITY PROBES

Sufficient time exists between the excitation and emission process in fluorescence spectroscopy for physical re-orientation of solvational sphere molecules. Physical re-orientation occurs as solvent molecules move to align their respective dipole moments with the new dipole moment of the excited fluorophore. Alignment of fluorophore–solvent dipole moments leads to more effective molecular interactions, which is reflected in a lower excited state energy level relative to the ground electronic state. Energy lowering increases with increasing fluorophore–solvent interactions and solvent polarity as depicted in Figure 3.[39] Most fluorescent probes have a much larger excited state than ground state dipole moment, hence the energy level of the ground state is affected to a much lesser extent. As a general rule-of-thumb the larger redshifts in emission band

Figure 3 Jablonski diagram showing solvent relaxation process: (- - - -) radiative process; (———) nonradiative process. (Redrawn with permission from T.L. Cecil and S.C. Rutan, *Anal. Chem.*, **62**, 1998–2004. Copyright (1990) American Chemical Society.)

wavelength(s) are observed in the more polar solvents. Emission wavelength(s) of fluorescent solvent polarity

probe molecules provides a quantitative measure of the polarity of the solubilizing solvent media.

Theoretical interpretation of solvatochromic wavelength shifts at the molecular level is very difficult, often subject to interpretation, and as one may surmise there have been numerous competing mathematical expressions published in the spectroscopic literature to explain observed wavelength shifts associated with known solute probes. To a first approximation specific effects are ignored. The energy difference (in cm^{-1}) between solvated ground and excited state fluorophore can be described by the Lippert equation (Equation 11):[40]

$$\frac{1}{\lambda_{ex}} - \frac{1}{\lambda_{em}} \approx \frac{2}{hc}\frac{(\mu^* - \mu)^2}{a^3} \times \frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{n^2 - 1}{2n^2 + 1} + \text{constant} \quad (11)$$

or modified forms such as Equation (12):

$$\frac{1}{\lambda_{ex}} - \frac{1}{\lambda_{em}} \approx \frac{2}{hc}\frac{(\mu^* - \mu)^2}{a^3} \times \frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{\beta(n^2 - 1)}{(2n^2 + 1)} + \text{constant} \quad (12)$$

where μ and μ^* refer to the ground state and excited state dipole moment, respectively, ε and n are the dielectric constant and refractive index of the solvent, c is the speed of light, h denotes Planck's constant, and a is the radius of the solvent cavity wherein the fluorophore resides. Equations (11) and (12) both imply a linear relationship between the observed Stokes shift, $1/\lambda_{ex} - 1/\lambda_{em}$, and a specific function of the solvent's refractive index and dielectric constant. The excited state dipole moment can be estimated through a linear least-squares regressional analysis of experimental Stokes shift data in accordance with Equation (11) (or 12).

Most fluorescent compounds do show some degree of solvatochromism as a result of molecular interactions with surrounding solvent molecules. The $(\mu^* - \mu)^2/a^3$ multiplicative factor in Equations (11) and (12) governs to a large extent the magnitude of the Stokes shift that the fluorophore experiences in going from a nonpolar to polar solubilizing medium. For fluorescent solvent polarity probes there generally is a large difference between the ground and excited state dipole moments, which leads to sizeable shift in the excitation and/or emission wavelengths. Coumarin-153 [53518-18-6], 4-amino-*N*-methylphthalimide [2307-00-8], 6-propionyl-2-(dimethylamino)naphthalene (PRODAN) [70504-01-7], 1-phenyl-4-(2-naphthylmethylene) piperidine (PNMP) [91759-51-2], 4-phenyl-4-(4-cyano-1-naphthylmethylene)piperidine (PCNMP) [91759-53-3] and the other compounds listed in Table 4 exhibit fairly large wavelength shifts in their recorded fluorescence spectrum as a function of solvent polarity. Each molecule listed has been recommended as a solvent polarity probe. Caution should be exercised in selecting a probe molecule for a particular application. Several molecules listed in Table 4 do contain acidic and/or basic functional groups; and as a result their spectral response may not necessarily be just to solvent polarity. Proton or charge transfer may contribute to the wavelength shift(s) for select solvents. Catalan et al.[53] issued a similar precaution when using PRODAN as an indicator of the polarity of protein cavities, particularly if the environments being examined contain acidic sites. The authors had to introduce a new acidic term into the Lippert equation to satisfactorily explain the observed absorption and emission spectroscopic behavior of PRODAN in several solvents.

6 FLUORESCENT TWISTED INTRAMOLECULAR CHARGE TRANSFER PROBES

Solvatochromic probe character can also result from charge-transfer induced dual fluorescence. Molecular systems that are known to exhibit such behavior include 9,9′-bianthracene (BA) [1055-23-8], 4-(9-anthryl)-*N*,*N*-dimethylaniline [38474-09-8], 4-(*N*,*N*-dimethylamino)benzonitrile [1197-19-9], ethyl 4-(*N*,*N*-dimethylamino)benzoate [10287-53-3] and *N*-arylcarbazoles. Theoretical treatments often assume equilibrium between the locally excited (LE) and twisted intramolecular charge transfer (TICT) species, which for BA is represented as[54] (Equation 13)

$$\underset{\text{TICT}}{An^+{-}An^-} \rightleftharpoons \underset{\text{LE}}{An{-}An^*} \rightleftharpoons \underset{\text{TICT}}{An^-{-}An^+} \quad (13)$$

with full electron/charge transfer separation. The two anthracene rings (denoted as An) twist to a perpendicular configuration to accommodate the separated charges. Fluorescence emission originates from LE and TICT excited states. The TICT band appears at longer wavelengths, and is more affected by solvent polarity/polarizability than is the LE band (see Figures 4 and 5). Emission band intensities are dictated by the fluorescent quantum yield and relative concentration of the two presumed isomeric species. More polar solvents like dimethyl sulfoxide favor the TICT species, and recorded emission spectrum in polar solvents often shows just the single TICT band. A bilinear Lippert relationship is generally seen in the case of TICT formation, with separate lines for each emission process.

p-Toluidinonaphthalene sulfonate (TNS) is also listed as fluorescent TICT probe. In water, where the polarity is high, the TICT rates of TNS are very large and

Table 4 Spectral properties of select fluorescent wavelength-shift solvent polarity probes

Probe/spectral properties	Probe/spectral properties
Coumarin-153[8,41] Nonpolar: $\lambda_{ex}/\lambda_{em} \approx 395/454$ nm Polar: $\lambda_{ex}/\lambda_{em} \approx 426/550$ nm	PNMP[8,46] Nonpolar: $\lambda_{em} \approx 361$ nm Polar: $\lambda_{em} \approx 523$ nm
4-Amino-*N*-methylphthalimide[8] Nonpolar: $\lambda_{em} \approx 410$ nm Polar: $\lambda_{em} \approx 606$ nm	PCNMP[8,46] Nonpolar: $\lambda_{em} \approx 412$ nm Polar: $\lambda_{em} \approx 695$ nm
N-Phenyl-1-naphthylamine[42] 1,4-Dioxane: $\lambda_{em} \approx 400$ nm Water: $\lambda_{em} \approx 462$ nm	PRODAN[47] Nonpolar: $\lambda_{em} \approx 401$ nm Polar: $\lambda_{em} \approx 531$ nm
Pyrene-1-carboxyaldehyde[43] Nonpolar: $\lambda_{em} \approx 408$ nm Polar: $\lambda_{em} \approx 475$ nm Linear λ_{em} versus ε (for $\varepsilon > 10$)	8-Anilino-1-naphthalene-sulfonic acid[48,49] Ethanol: $\lambda_{em} \approx 464$ nm Water: $\lambda_{em} \approx 523$ nm 200-fold increase in ϕ_f in 1-octanol versus water
2,3-(Dihydro-1-methyl-4(1*H*)-quinolinylidene)propanedinitrile[8] Nonpolar: $\lambda_{em} \approx 500$ nm Polar: $\lambda_{em} \approx 588$ nm	Coumarin-311[50] Nonpolar: $\lambda_{em} \approx 373$ nm Polar: $\lambda_{em} \approx 444$ nm
1,9-Di(*N*-phenyl-*N*-methyl)-4,6-dimethylenenona-1,3,6,8-tetraen-5-one[44] Toluene: $\lambda_{ex}/\lambda_{em} \approx 452/491$ nm Water: $\lambda_{ex}/\lambda_{em} \approx 552/610$ nm	2-(*p*-Toluidino)naphthalene-6-sulfonate[51] Dioxane: $\lambda_{em} \approx 413$ nm Water: $\lambda_{em} \approx 500$ nm Large increase ϕ_f in organic solvents versus water
Coumarin-102[45] $\Delta(1/\lambda_{ex}) \approx 1.47 \times 10^3$ cm^{-1} $\Delta(1/\lambda_{em}) \approx 2.94 \times 10^3$ cm^{-1} Dimethyl sulfoxide–cyclohexane	Nile red[52] Nonpolar: $\lambda_{ex}/\lambda_{em} \approx 484/529$ nm Water: $\lambda_{ex}/\lambda_{em} \approx 591/657$ nm

the fluorescent quantum yield is very small, i.e. $\phi_f \approx 0.001$. The TICT process in the case of this particular fluorescent probe is nonradiative. When TNS binds to the nonpolar, hydrophobic surfaces of micelles, proteins or apolar CD cavities, the TICT process is inhibited. This causes a dramatic increase in the fluorescent quantum yield. The fluorescence intensity enhancement

thus provides direct information about polarity of the microenvironment in the immediate vicinity of the TNS probe molecule.

The following examples illustrate the type of information that can be obtained with TICT probe molecules. Kajimoto and coworkers[55] used fluorescence emission from the TICT state of 4-(*N*,*N*-dimethylamino)benzonitrile to investigate solvent structure in the cybotactic region of supercritical trifluoromethane. Experimental measurements revealed that both the Stokes shift and calculated F_{TICT}/F_{LE} emission intensity ratio increased with increasing fluid density. Observed spectral wavelength shifts were compared to values predicted from theoretical models that assume a homogeneous dielectric solvent. Analysis of the experimental data indicated that near the critical point the local solvent density around the probe molecule was greater than the bulk solvent. The CHF_3 solvent molecules were not uniformly dispersed, but rather tended to aggregate around the fluorophore. At low densities, the number of solvent molecules within the fluorophore's solvational sphere depended linearly upon the bulk solvent density. More recently, TICT probes 4-(*N*,*N*-dimethylamino)benzonitrile and ethyl 4-(*N*,*N*-dimethylamino)benzoate were used to study interactions in supercritical trifluoromethane and carbon dioxide at different solvent compositions.[56]

TICT probes can examine structural features inside CD cavities. The most widely used CD molecules contain six, seven and eight glucose monomers arranged in toris shapes, and are named α-, β- and γ-CD, respectively. Coupling of the glucose molecules gives the CD a rigid, conical molecular structure with a hollow hydrophobic interior that enables the CDs to trap probe molecules based upon molecular shape/size compatibility. γ-CD is the larger of the commercially available CDs, having an internal diameter of approximately 9.5 Å and depth of roughly 7.8 Å. Published fluorescence measurements indicate that LE and TICT electronic states of 4-(*N*,*N*-dimethylamino)benzonitrile form 1 : 1 guest–host inclusion complexes with β-CD. The two electronic states reside in different microenvironments within the cavity.[57]

7 FLUORESCENT POLYCYCLIC AROMATIC HYDROCARBON SOLVENT POLARITY PROBES

Pertinent photophysical processes governing fluorescence behavior of polycyclic aromatic hydrocarbons (PAHs) dissolved in fluid solution are summarized below:

$$PAH + h\nu_0 \longrightarrow PAH^* \quad \text{(absorption/excitation)}$$
$$PAH^* \longrightarrow PAH + h\nu_1 \quad \text{(emission)}$$
$$PAH^* + PAH \longrightarrow (PAH)_2^* \quad \text{(excimer formation)}$$
$$(PAH)_2^* \longrightarrow 2PAH + h\nu_2 \quad \text{(excimer emission)}$$

Emission spectrum of PAH monomer consists of several major vibronic bands labeled I, II, III, etc., in progressive order, starting with the O–O vibronic band. Published studies[58–60] revealed that Py, benzo[*ghi*]perylene (BPe) [191-24-2], ovalene (Ov) [190-26-1], coronene (Co) [191-07-1], benzo[*a*]coronene (BCo) [190-7-5], naphtho-[2,3*a*]coronene (NCo) [190-74-9], dibenzo[*a*, *j*]coronene (DCo) [190-72-7], benzo[*e*]pyrene (BePy) [192-97-2], 3,4-dihydrobenzo[*ghi*]perylene (DHBPe) [16310-65-9], benzo[*rst*]pentaphene (BPP) [189-55-9], methylcoronene (MeCo) [13119-86-3], 1,2-dimethylcoronene (DiMeCo) [113523-79-8] and several other PAHs exhibit selective emission intensity of vibronic band I relative to band III (or band IV) in polar solvents (see Figure 6). Ratios of band I and III (or IV) serve as quantitative measure of solvent polarity and structure. Less than 25% of the PAH solutes studied to date exhibit probe character. Emission intensity ratios for the majority of PAHs remain essentially constant, irrespective of solvent polarity.

Tables 5 and 6 list experimental emission intensity ratios for Py, BPe, Co, BePy, DHBPe, Ov, MeCo and DiMeCo dissolved in select nonelectrolyte solvents. Careful examination of the entries in Table 7 reveals that, for the most part, the rank ordering of solvents by polarity is identical for the eight PAH probes. Linear least-squares analysis of the intensity ratio data shows that the polarity scales are highly correlated as indicated by the squared correlation coefficient, r^2.

Of the known PAHs that exhibit selective emission intensity enhancement, the eight molecules listed above are the ones recommended for solvent polarity

Figure 6 Fluorescence emission spectra for Co dissolved in dimethyl sulfoxide (A), methanol (B), carbon tetrachloride (C) and cyclohexane (D). For illustrational purposes, the four emission spectra have been normalized to the emission intensity of the III band. The Co solvent polarity scale is defined as the I(at 426–430 nm)/III(at 445–449 nm) emission intensity ratio.

Dynamic range	1.37	0.98	0.86	2.08

[a] Experimental Py values are taken in part from Dong and Winnik[58] and are based upon the properties of Py.
[b] Defined as the ratio of band I (≈405 nm)/band III (≈417 nm) for benzo[*ghi*]perylene.
[c] Defined as the ratio of band I (≈424 nm)/band III (≈445 nm) for Co.
[d] Defined as the ratio of band I (≈480–485 nm)/band III (≈500–505 nm) for Ov.

determinations. The eight PAHs have various shapes and different excitation wavelength(s). Depending upon the spectral characteristics of the organic solvent and/or molecular shape/size constraints imposed by the organized solvent media being examined, one PAH probe may be preferred from an experimental standpoint.

Py solvent polarity scale is defined as the F_1/F_3 emission intensity ratio, where band I corresponds to $S_1(v = 0) \rightarrow S_0(v = 0)$ transition and band III is a $S_1(v = 0) \rightarrow S_0(v = 1)$ transition. Karpovich and Blanchard[61] rationalized Py's solvatochromic behavior in terms of vibronic coupling between the weakly allowed Py first electronic excited singlet state ($\varepsilon_{max} \approx 200\,cm^{-1}\,M^{-1}$) and the strongly allowed second electronic singlet state. The observed Py absorption/excitation spectrum involves $S_0 \rightarrow S_2$ electronic transition. The nonprobe perylene molecule, on the other hand, exhibits the typical excitation–emission mirror image symmetry common to many PAHs. Perylene absorption/excitation spectrum corresponds to the ground state → first electronic excited state transition ($\varepsilon_{max} \approx 33\,000\,cm^{-1}\,M^{-1}$ for $S_0 \rightarrow S_1$).

Vibrationally mediated coupling between electronic S_1 and S_2 states can be mathematically described through both Herzberg–Teller (HT) and Born–Oppenheimer (BO) contributions. Equations derived by Karpovich and Blanchard indicate that the magnitude of nuclear displacement along the coupling coordinate is sensitive to the dipolar and dielectric properties of surrounding solvent media. Vibronic coupling contributions to the O–O absorption and emission cross-sections scale as HT + BO and HT − BO contributions, respectively. For a two level system, such as the O–O Py transition, cross-sections for the absorption and emission processes must be equal. Hence, $(HT + BO)_{O-O} = (HT - BO)_{O-O}$, and I band intensity depends solely upon the HT coupling between S_2 and S_1 electronic states. Band III corresponds to a $S_1(v = 0) \rightarrow S_0(v = 1)$ electronic transition, with its emission intensity being determined by the difference between

Table 6 Ratios of fluorescence emissions of BePy, DHBPe, MeCo and DiMeCo in various organic solvents

[a] Defined as ratio of band I (≈376 nm)/band IV (≈408 nm) for BePy.
[b] Defined as the ratio of band I (≈380 nm)/band II (≈390 nm) for DHBPe.
[c] Defined as the ratio of band I (426–429 nm)/band III (444–448 nm) for MeCo.
[d] Defined as the ratio of band I (428–432 nm)/band III (447–450 nm) for DiMeCo.

Table 7 Ordering of solvents by polarity

BPe = 0.674 Py + 0.109	($r^2 = 0.932$)
Co = 0.550 Py − 0.136	($r^2 = 0.956$)
Ov = 1.356 Py − 0.331	($r^2 = 0.941$)
BePy = 1.034 Py − 0.058	($r^2 = 0.963$)
DHBPe = 0.687 Py + 0.773	($r^2 = 0.956$)
MeCo = 0.692 Py + 0.393	($r^2 = 0.965$)
DiMeCo = 0.772 Py + 1.082	($r^2 = 0.936$)

the HT and BO contributions. This difference is less solvent dependent than each of the separate HT and BO contributions. The F_1/F_3 emission intensity ratio thus increases with increasing solvent polarity.

Fluorescent PAH solvent polarity probes have been used in applications ranging from the determination of critical micelle concentrations, to measurement of solvent polarity of gas–liquid chromatographic (GLC) and HPLC stationary phases to estimation of preferential solvation in binary solvent mixtures. In this latter application, most published approaches assume that a given fluorophore's solvational sphere contains just solvent molecules A. Other fluorophore molecules in the solution would be solvated completed by solvent component B. Each solvated fluorophore contributes to the observed fluorescence signal, F_{obs}, at each emission wavelength scanned. Emission intensities are additive at each wavelength. In the case of a PAH probe such as Py, the calculated F_1/F_3 emission intensity ratio is[62] given by the Equation (14):

$$\frac{F_1}{F_3} \approx [Y_A F_{1,\text{phase A}} + (1 - Y_A) F_{1,\text{phase B}}] + [Y_A F_{3,\text{phase A}} + (1 - Y_A) F_{3,\text{phase B}}] \quad (14)$$

Here, [Fluoro] is the total stoichiometric fluorophore molar concentration, and Y_A and $(1 - Y_A)$ represent the mole number fraction of each type of solvated fluorophore, i.e. $Y_A = [\text{Fluoro A}] \div [\text{Fluoro}]$ and $(1 - Y_A) = [\text{Fluoro B}]/[\text{Fluoro}]$. Solute concentration must be

maintained constant for all fluorescence measurements. Equation (14) does accurately reproduce fluorescence behavior of Py, DHBPe, Co and BePy dissolved in *n*-heptane + 1,4-dioxane and *n*-heptane + tetrahydrofuran mixtures. Calculated Y_A values indicated that the PAH solute probe was preferentially solvated by the nonpolar *n*-heptane cosolvent, with the degree of preferential solvation decreasing with increased PAH molecular size.[62]

Modified forms of the general spectral response equation have been used successfully in the calculation of equilibrium constants for PAH–CD complex formation, and in the calculation of binding constants for PAH–surfactant complexation. As a classical example, Xu et al.[63] examined interactions between Py and α- and β-CD and/or polymerically linked β-CDs. Experimental fluorescence emission intensity versus CD concentration curves were analyzed in terms of four existing literature models. Of the models considered only the one assuming sequential formation of 1:1 and 1:2 Py–CD complexes, with each complex being fluorescent and having different F_1/F_3 emission intensity ratios, was found to describe the monomeric CD data satisfactorily. At each emission wavelength scanned, the observed fluorescence signal, F_{obs}, is the sum of the emission intensities from the Py monomer and two fluorescent Py–CD complexes. The measured I and III band emission intensities are given by Equations (15) and (16):

$$F_1 = f_{Py}F_{1,Py} + f_{Py-CD}F_{1,Py-CD} + f_{CD-Py-CD}F_{1,CD-Py-CD} \quad (15)$$

$$F_3 = f_{Py}F_{3,Py} + f_{Py-CD}F_{3,Py-CD} + f_{CD-Py-CD}F_{3,CD-Py-CD} \quad (16)$$

where f is the fraction of Py existing as the uncomplexed Py, 1:1 and 1:2 Py–CD complexes. The four emission intensities involving the Py–CD complexes cannot be experimentally determined because each PAH–CD complex must be in equilibrium with the *uncomplexed* PAH monomer. To circumvent this problem, Equation (15) is recast as Equation (17):

$$F_1 = f_{Py}\left(\frac{F_1}{F_3}\right)_{Py} F_{3,Py} + f_{Py-CD}\left(\frac{F_1}{F_3}\right)_{Py-CD} F_{3,Py-CD} + f_{CD-Py-CD}\left(\frac{F_1}{F_3}\right)_{CD-Py-CD} F_{3,CD-Py-CD} \quad (17)$$

using F_1/F_3 emission intensity ratios, equilibrium constants and F_3 values which scale the calculation to the observed data. The various fractions were expressed in terms of the two equilibrium constants, uncomplexed Py and CD concentrations. Through a global fitting of F_1 and F_3 data simultaneously, optimized numerical values of the equilibrium constants were calculated.

The number of required input parameters (e.g. fluorescence emission properties) is reduced through simplifying approximations. Examination of Equation (14) reveals that the measured F_1/F_3 emission intensity ratio for a PAH probe dissolved in a binary solvent mixture (or alternatively, for a PAH probe dissolved in two different microenvironments) becomes Equation (18):

$$\frac{F_1}{F_3} = Y_A\left(\frac{F_1}{F_3}\right)_{\text{phase A}} + (1 - Y_A)\left(\frac{F_1}{F_3}\right)_{\text{phase B}} \quad (18)$$

a weighted average of the measured emission intensity ratios in each pure solvent, $(F_1/F_3)_{\text{phase A}}$ and $(F_1/F_3)_{\text{phase B}}$, provided that probe's measured III band intensity is identical in both neat solvents (or microenvironments/phases). Equation (18) requires knowledge of only the F_1/F_3 emission intensity ratio for each different solvational species, rather than individual emission intensities at two different wavelengths. This reduces the number of input parameters by a factor of two, and eliminates in part experimental artifacts that might result from each solution having a slightly different analytical concentration of the dissolved PAH probe molecule. Recent studies addressed influences that chiral modifiers, diols and amines have in regards to Py–CD complexation. Complexation between Py and derivatized-CDs and between Py and cationic surfactant headgroups have been studied by fluorescence probe methods, several of which were based upon Equation (18).

8 FLUORESCENT ANISOTROPIC AND MICROVISCOSITY PROBES

Fluorescence anisotropic measurements provide valuable information in regards to the fluorophore's orientational and rotational motions. Anisotropy is an angular correlation function that describes the mutual orientation of both the absorption and emission transition dipole moments at the times of excitation ($t = 0$) and emission ($t = t$). Fluorophores whose absorption dipoles are aligned with the electric vector of the excitation radiation have the highest probability of excitation when irradiated with polarized light. Photoselection rules dictate that the resulting fluorescence must also be polarized. Fluorescence does not occur immediately. There is sufficient time for the fluorophore to rotate during the excited state lifetime. Some depolarization occurs as a result of rotational motion. The magnitude of the depolarization depends upon the fluorophore's molecular size and shape, as well as upon the viscosity of the microenvironment in the fluorophore's immediate vicinity. Fluorescence

polarization measurements have been used to investigate ligand binding, protein denaturation and surfactant aggregation.

In steady-state fluorescence anisotropic studies, spectra are acquired by scanning wavelengths selected by an excitation monochromator, and then measuring the emission intensity parallel, $F_{\parallel}$, and perpendicular, $F_{\perp}$ to the polarization of the excitation radiation. Mathematically, the degree of polarization and the anisotropy are defined by Equations (19) and (20):

$$P = \frac{F_{\parallel} - F_{\perp}}{F_{\parallel} + F_{\perp}} \tag{19}$$

$$r = \frac{F_{\parallel} - F_{\perp}}{F_{\parallel} + 2F_{\perp}} \tag{20}$$

The above definitions also hold for time-resolved fluorescence measurements. Emission intensities would now be time-dependent functions, $F_{\parallel}(t)$ and $F_{\perp}(t)$, as opposed to an actual numerical value. Correction terms can be added to eliminate effects from stray radiation.

It can be shown that the initial ($t = 0$) and maximum value of the anisotropy, r_0, is 2/5 for any macroscopically isotropic orientational distribution of fluorophore molecules. This is of course the theoretical limiting value that one expects to observe in systems where rotational motions become negligible. The limiting value is never observed, however, not even in systems where the temperature has been lowered to restrict rotational motions. The smaller experimental r_0 values have been explained in terms of torsional vibrations of the fluorescent molecules about their equilibrium orientation, combined with perhaps a small rotation of the absorption and emission dipoles due to coupling with vibrational modes. Since the theoretical value is never realized, the operational definition of the limiting fluorescence anisotropy is the maximum value that is experimentally measured.

Popular fluorescent anisotropic probe molecules include: perylene [198-55-0], PRODAN, 1,4-diphenylbuta-1,3-diene [886-65-7], 1,6-diphenylhexa-1,3,5-triene [1720-32-7], anthracene [120-12-7], 2-methylanthracene [613-12-7], 9-vinylanthracene [2444-68-0], potassium 2-(*p*-toluidino)naphthalene-6-sulfonate [32752-10-6], rhodamine B [81-88-9], rhodamine 6G [989-38-8], rhodamine 101 [41175-43-3], fluorescein [2321-07-5], 2,5,8,11-tetra-*tert*-butylperylene (TBP) [80663-92-9] and 9-(3-perylenoyl)nonanoic acid. Spectral properties of selected probes are listed in Table 8. Each molecule contains a fluorescent moiety. Functional groups are added to modify the molecule's rotational motion and to provide a means of judiciously controlling location of the probe within a molecularly-organized, biological and/or membrane system. Polar and ionic functional groups increase the probe's aqueous solubility.

Fluorescent anisotropic probe methods provide a convenient experimental technique for determining microviscosity of molecularly-organized structures. If rotational diffusion is the main cause of anisotropy loss, then observed anisotropy is related to the microviscosity, η, by the Perrin equation (Equation 21):

$$r = \frac{r_0}{1 + (\tau kT/\eta V)} \tag{21}$$

where k is the Boltzmann constant, T denotes the absolute Kelvin temperature, and V and τ refer to the effective molecular volume and fluorescence lifetime of the probe, respectively. Equation (21) applies to a spherical rotor, and in several published applications V was assumed to have a functional dependence upon r. Calibration curves of measured r_0/r values versus known $\tau T/\eta$ values are available for several probes.[66] More complex expressions have been derived for nonsymmetric species or molecules.

Microviscosities have been estimated using ratio of intramolecular excimer to monomer fluorescence emission intensities (i.e. $F_{\text{excimer}}/F_{\text{monomer}}$). The method involves construction of a calibration curve by measuring $F_{\text{excimer}}/F_{\text{monomer}}$ ratios in solutions of known viscosity since there is no theoretical relationship for how the emission intensity ratio should vary with η. As a cautionary note, calibration curves should be established under isothermal experimental conditions. Excimer formation is affected by temperature, and changes in measured $F_{\text{excimer}}/F_{\text{monomer}}$ ratio forms the basis for fluorescent thermometer development. 1,3-Di(α-naphthyl)propane[78,79] [14564-86-4] and bis(4-biphenylmethyl)ether[80] [68941-68-4] are recommended probe molecules for the $F_{\text{excimer}}/F_{\text{monomer}}$ method. Microviscosity determinations using intermolecular excimer formation are generally not as effective, particularly in molecularly organized solvent structures such as micelles. It is much easier to control micellar fluorophore distribution leading to excimer formation whenever the two chromophoric moieties are contained within the same molecule.

Perylene initially was identified as an anisotropic rotator in steady-state polarization measurements. Wavelength-dependent Perrin plots indicated the presence of at least two rotational motions, which were confirmed by subsequent time-resolved fluorescence techniques. Rate of rotation of perylene about its major symmetry axis (z-axis) is an order of magnitude greater than the rate of rotation perpendicular to the z-axis. Time-resolved fluorescence anisotropies of perylene are generally characterized by a double-exponential model. Calculated rotational decay times can be related to the diffusion about the in-plane and out-of-plane molecular axis.

Table 8 Spectral properties of select anisotropic and microviscosity probes

Probe/property	Probe/property
1,4-Diphenylbuta-1,3-diene $\lambda_{ex} = 295$ nm $\lambda_{em} = 420$ nm $V = 205$ Å^3[64]	PRODAN $\lambda_{ex} = 351$ nm; $r_0 = 0.336$[72] $\lambda_{em} = 385$ nm (solvent dependent)

TBP $\lambda_{ex} = 272$ nm, $r_0 = -0.160$[70] $\lambda_{ex} = 416$ nm, $r_0 = 0.389$[70] $\lambda_{em} = 440-480$ nm	*N*,*N*-bis(2,5-*tert*-butylphenyl)-3,4,9,10-perylenetetracarboximide $\lambda_{ex} = 514.5$ nm; $r_0 = 0.382$[75] $\lambda_{ex} = 520$ nm; $r_0 = 0.37$[76] $\lambda_{em} = 580$ nm
4-Amino-4′-nitrostilbene $r_0 = 0.3125$[71] $V = 1533$ Å^3[71]	1-Dimethylaminonaphthalene-5-sulfoamide $\lambda_{ex} = 360$ nm; $r_0 = 0.33$[77]
	4-Dimethylamino-4′-nitrostilbene $r_0 = 0.3278$[71] $V = 1724$ Å^3[71]

Rotational decays become equal, however, if four *tert*-butyl groups are substituted symmetrically into perylene. Anisotropy decay of TBP is monoexponential.[70]

The following representative examples illustrate the type of information that anisotropic probes can provide. Jobe and Verrall[64] employed polarized fluorescence emission to determine microviscosity of ternary mixtures containing 2-butoxyethanol, cetyltrimethylammonium bromide (CTAB) and water. Diphenylbutadiene was used as anisotropic probe molecule. Strong columbic binding prevented the authors from using potassium 2-(*p*-toluidino)naphthalene-6-sulfonate. At fixed surfactant concentration, the microviscosity was found to decrease with increasing 2-butoxyethanol concentration. The polar alkoxyalcohol effectively penetrated into the palisade region causing the CTAB micelle to swell. As part of the investigation the microviscosity of aqueous CTAB, sodium dodecyl sulfate (SDS), tetradecyltrimethylammonium bromide (TTAB) and cetylpyridinium bromide (CPyB) were also determined. Calculated values ranged from $\eta \approx 14$ cP to $\eta \approx 29$ cP, and were in excellent agreement with published values based upon the polarized fluorescence behavior of anthracene and 2-methylanthracene.

Betts et al.[72] estimated solute–fluid cluster sizes in supercritical N_2O based upon the measured fluorescence anisotropic and lifetime data for the probe molecule PRODAN. Measured steady-state anisotropies in supercritical N_2O decreased with increasing pressure, whereas in liquid N_2O the observed anisotropy remained essentially constant. Two limiting cases were considered. In the first case, the authors assumed only minimal interaction between the probe PRODAN and surrounding N_2O solvent molecules. The probe was free to rotate within the locally enriched solvent cluster environment. Strong probe–solvent interactions were assumed in the second model. Probe plus cluster was now treated as a single rotating body. Analysis of experimental data within this framework yielded an average cluster size containing

between 25 and 103 N_2O molecules near the critical pressure.

More recently, time-resolved anisotropic measurements[81] have been utilized to examine rotational reorientation dynamics of Aerosol-OT reverse micelles formed in near-critical propane solvent. Cationic anisotropic probes rhodamine 6G and rhodamine 101 were solubilized within the reverse micelle. Experimental data were interpreted using a bi-exponential rate law expression, with the rotational correlation times describing both the independent lateral rotation diffusion of the fluorophore along the water–headgroup interfacial region within the reverse micelle and the global rotational motion of the entire micelle. Rotational correlation times for the micelle were 40 times slower than expected, and suggested the formation of micelle–micelle aggregates. The study complemented the authors' earlier work involving rotational motion of several xanthene dyes (rhodamine 6G, rhodamine B, rhodamine 101 and fluorescein). Here, probes were solubilized in Aerosol-OT reverse micelles formed in heptane.

9 FLUORESCENT TEMPERATURE PROBES

Fluorescence-based temperature sensing is becoming increasingly more popular for monitoring processes occurring in microscopic and hostile environments where conventional thermometry is either impractical or impossible. Temperature-sensitive fluorescent probes provide a relatively nonintrusive method to study biological cells. Published applications include temperature measurement in evaporating fuel sprays and burning flames, examination of temperature fluctuations on surfaces of turbine engines and monitoring dynamic heat transfer in chemical reactions. In each application, a systematic change was observed in spectral properties of the probe molecule with increasing/decreasing temperature. Observed spectral changes were generally manifested as either shifts in the emission wavelength(s) or variations in measured intensities of selected emission bands caused by thermal excitation of vibronic states in the electronic excited state (i.e. fluorescence hot-band emission), changes in the microenvironment's refractive index and dielectric constant, or by differences in the monomer/excimer (or monomer/exciplex) concentration ratio in systems where excimer (or exciplex) formation occurs.

Accurate temperature determination requires that measured fluorescence spectra be free of inherent fluctuations in the intensity of the excitation radiation source and other instrumental artifacts. Strategies that have proved successful in this regard have involved the design of probe molecules having two fluorescent moieties or the utilization of molecules that exhibit an emission intensity enhancement of select vibronic bands. The emission intensity of the non-enhanced band(s) would serve as an internal reference point, thus reducing the problems associated with measurements based upon a single emission process.

Of the probe molecules that have been suggested as fluorescent thermometers, *N*-(1-pyrenylmethyl)-1-pyrenebutamide (PMPBA) [187589-23-7] and *N*-(1-pyrenylmethyl)-1-pyreneacetamide (PMPAA) [187589-24-8] are perhaps the most versatile for applications between ambient room temperature and 100 °C.[82] The two pyrenyl fluorophoric centers give each molecule a high quantum yield and good sensitivity. As shown in Figure 7 the intramolecular excimer emission (which is centered around $\lambda_{em} \approx 448$ nm in the case of PMPBA) decreases with increasing temperature. Normalization of excimer emission signals to those of the monomer eliminates the effects caused by excitation source fluctuations and variations in fluorophore concentrations and optical pathlength. Measured natural logarithm of $F_{excimer}/F_{monomer}$ emission intensity ratio versus reciprocal of the absolute Kelvin temperature, $1/T$, is nearly linear over the entire recommended temperature range. Lou et al.[82] estimated the precision of temperature measurement to be within $\Delta T = \pm 0.7$ °C and $\Delta T = \pm 0.8$ °C for PMPBA and PMPAA, respectively (see Figure 8). 1,3-Bis-(1′-pyrenyl)propane (PyPyP) [61549-24-4] and 3-(4′-dimethylaminophenyl)-1-(1′-pyrenyl)propane (PyDMAP) [38764-41-9] can be used for measuring temperatures above 100 °C. The latter two molecules also exhibit temperature-dependent

Figure 7 Observed fluorescence emission spectra of 0.33 μM PMPBA dissolved in dodecane as a function of temperature. Spectra have been normalized to the intensity of the monomer band, which occurs at about 396 nm. (Redrawn from J. Lou, T.A. Hatton, P.E. Laibinis, *Anal. Chem.*, **69**, 1262–1264. Copyright (1997) American Chemical Society.)

Figure 8 Relationship between F_E/F_M and temperature for 0.33 μM solutions of fluorophores PMPBA and PMPAA in dodecane. (Redrawn from J. Lou, T.A. Hatton, P.E. Laibinis, *Anal. Chem.*, **69**, 1262–1264. Copyright (1997) American Chemical Society.)

$F_{excimer}/F_{monomer}$ (PyPyP) and/or $F_{exciplex}/F_{monomer}$ (PyDMAP) fluorescent behavior. Both compounds are reported to be thermally stable for 10–20 minutes at temperatures of 300–400 °C.[83]

1,4-Di[2-(5-phenyloxazoyl)]benzene [1806-34-4], 2-(1-naphthyl)-5-phenyloxazole [846-63-9], *N*,*N*-bis(2,5-di-*tert*-butylphenyl)-3,4,9,10-perylene dicarboximide [83054-80-2] and BPe (to a much lesser extent) have been recommended as fluorescent temperature probes for measurements in the 25–170 °C range. Temperature is determined from nearly linear plots of $R_n(t)$ versus temperature [where $R_n(t)$ is the ratio of integrated emission intensity in the blue range to that in the red range at the system temperature T, normalized to the emission intensity ratio measured at ambient room temperature]. All four of the suggested probe molecules exhibit high fluorescent quantum yields and are insensitive to quenching by molecular oxygen. Expected temperature resolution is approximately ±4 °C.[84]

Fluorescent thermometers have been developed for measuring flame temperatures using anomalous $S_0 \leftarrow S_2$ fluorescence emission of isolated Py molecules.[85–87] Emission intensity ratio for the $S_0 \leftarrow S_2$ and $S_0 \leftarrow S_1$ spectral transitions is known to depend strongly upon both excitation and temperature. At low temperatures (425–625 K) and pressures (less than 50 torr) fluorescence emission is related directly to the internal vibrational temperature of the Py molecules. A plot of logarithm of S_2/S_1 emission intensity ratio versus the reciprocal of absolute Kelvin temperature is linear over the 425–625 K temperature region. Py is an organic molecule and it does undergo chemical reactions in the more oxidative flames, which limit its applicability to nonoxidative environments. Suggested systems that could be monitored with a Py probe molecule include high-temperature exhausts, diffusion flames and nonreactive flows of interest in heat transfer and fluid mechanics.

In recent years temperature measurements have also been performed with fluorescent probes that exhibit systematic shifts in emission wavelengths with temperature. Extreme caution should be exercised in using this type of probe molecule since it has not yet been conclusively established that the observed emission wavelength response depends solely upon temperature. Changes in solvent properties also contribute to the observed fluorescent behavior as discussed in the section devoted to fluorescent solvent polarity probes. It is quite conceivable that changes in the solvent's refractive index and/or dielectric constant may have contributed in part to observed probe character. Both dielectric constant and refractive index are temperature-dependent, and calibration curves established in one solvent media might not be transferable to another solvent media or molecularly organized system. Until this point is satisfactorily addressed it is recommended that the calibration curve relating the observed emission wavelength and temperature be made in a solvent whose physical properties closely mimic those of the intended application. This should help in minimizing any affects arising from changes in solvent properties brought about by temperature change.

10 FAR-VISIBLE AND NEAR-INFRARED ABSORPTION AND LUMINESCENT PROBES

Far-VIS and near-infrared absorption and luminescent probes[88,89] are currently used in biological and medical applications as in vivo sensors/tracers. Few biologically active molecules absorb in the 600–1000 nm spectral region, and attachment of a near-infrared probe molecule

Table 9 Spectral properties of select near-infrared probes

Probe/property	Probe/property
Noncovalent binding probes:	3,3′-Diethyloxatricarbocyanine iodide
cyanine iodide	$\lambda_{abs} = 677\,nm$[90]
$\lambda_{ex} = 746\,nm$	3,3′-Diethyloxadicarbocyanine iodide
$\lambda_{ex} = 775\,nm$[90]	$\lambda_{abs} = 577\,nm$[90]
3,3′-Diethythiadicarbocyanine iodide	Laser dye IR-125
$\lambda_{abs} = 646\,nm$[90]	$\lambda_{abs} = 780–786\,nm$[95]
Indocyanine Green	Squarilium dyes
$\lambda_{ex} = 780\,nm$	$\lambda_{abs} = 655–850\,nm$[89,96]
$\lambda_{ex} = 830\,nm$[91]	Croconium dyes
bis-Indole derivatives of	$\lambda_{abs} = 715–950\,nm$[89]
Heptamethine cyanines	NK-427 Dye
$\lambda_{abs} = 780–810\,nm$[92]	$\lambda_{ex} = 823\,nm$
bis-Benzindole derivatives of	$\lambda_{em} = 850\,nm$[97]
heptamethine cycanines	Transesterified derivatives of
$\lambda_{abs} = 750–830\,nm$[92]	laser dye IR-144
Covalent bonding probes:	$\lambda_{ex} = 755–796\,nm$
Laser dye IR-144	$\lambda_{ex} = 815–820\,nm$[93]
$\lambda_{ex} = 742\,nm$	BTPHB
$\lambda_{ex} = 819\,nm$[93]	$\lambda_{abs} = 698\,nm$ in water[95]
Isothiocyanato-analogs of	$\lambda_{abs} = 811\,nm$ in methanol[95]
Indocyanine Green	
$\lambda_{abs} = 780–790\,nm$[94]	

BTPHB, 2-[4′-chloro-7′(3″-ethyl-2″-benzothiazolinylidenyl)-3′,5′-(1‴,3‴-propanediyl)-1′,3′,5′-heptatriene-1′-yl]-3-ethylbenzothiazolium bromide.

provides a means to label the analyte molecule of interest. Near-infrared probes typically possess large molar absorptivities ($\varepsilon \approx 200\,000\,cm^{-1}\,M^{-1}$) and reasonably good quantum yields ($\phi_F \approx 0.8$), which facilitate spectrophotometric detection. Detection limit depends entirely upon spectral characteristics of the probe molecule and instrumentation capability. Background corrections for sample absorbance and/or fluorescence are negligible.

Molecules that exhibit long-wavelength absorption and emission generally have extensive delocalized double-bond conjugation. Two major families of molecules known to have long-wavelength absorption maxima are polymethine cyanine and phthalocyaninine dyes. These dyes are practically insoluble in nonpolar organic solvents because of their ionic character; however, they do dissolve in most polar organic solvents and binary aqueous–organic mixtures. Polar and ionic functional groups can be added to judiciously alter molecules' spectral properties and water solubility, or to provide a site for analyte attachment. Attachment involves either noncovalent binding or covalent bonding as in the case of a biological molecule, or complexation to a metal ion. For example, water solubility can be enhanced by the presence of a sulfonate group, whereas an added isothiocyanate group would allow the probe molecule to be selectively attached to the amino groups of proteins. Thiourea bond that would be formed is quite stable above a pH of 6.0. Several near-infrared probes are listed in Table 9, along with their spectral properties.

Far-VIS and near-infrared absorbing dyes have only recently been introduced into analytical chemistry, and their applications as spectroscopic probes have not yet been fully realized. Patonay and coworkers[95] explored the feasibility of using polymethine cyanine dyes as solvent polarity probes, based upon their aggregation tendency in binary aqueous–alcohol mixtures. Of the four dyes studied, only IR-144 [54849-69-3] and BTPHB showed any real noticeable spectral change with solvent composition. The effect was more dramatic for BTPHB in that over a 110 nm shift was observed in the absorption maxima wavelength between water ($\lambda_{abs} \approx 698\,nm$) and neat methanol ($\lambda_{abs} \approx 810\,nm$). Recorded absorption spectra contained two peaks at intermediate binary solvent compositions as shown in Figure 9. Peaks were well-resolved and required no deconvolution to accurately quantify. The peak at $\lambda_{abs} \approx 698\,nm$ was attributed to formation of dimers (or perhaps higher associated aggregates). The authors suggested that the calculated $A_{monomer}/(A_{monomer} + A_{dimer})$ absorbance ratio could serve as a useful measure of *solvent hydrophobicity*. Previously, it had been reported[97] that the fluorescent lifetime of the polymethine dye 3,3′-diethyl-2,2′-(4,5 : 4′,5′-dibenzo)dithiatricarbocyanine iodide (NK-427) [20682-18-2] was highly correlated with solvent dielectric constant. Further experimental research is needed,

Figure 9 Representative spectra of BTPHB in water (———), and 20% (– – – –), 30% (++++), 40% (· · · ·) and 50% (– · —·) methanol. (Redrawn with permission from G. Patonay, M.D. Antoine, S. Devanthan, L. Strekowski, *Appl. Spectrosc.*, **45**, 457–461. Copyright (1991) Society for Applied Spectroscopy.)

however, to firmly establish the BTPHB and NK-427 scales as meaningful measures of solvent hydrophobicity.

To date, less than a dozen near-infrared dyes have been used as probe molecules in actual pH measurements. Published examples include pH determinations based upon measured emission intensities of three immobilized tetrasubstituted chloroaluminum 2,3-naphthocyanine dyes[98] [functional groups were $(5\text{-NC})_4-$, $(5\text{-O}_2\text{N})_4-$ and $(5\text{-HOOC})_4-$] and a bis(carboxylic acid) derivative of 2′{4′-chloro-7′-[2″-(1″-ethyl-3″,3″-dimethylindoleninylidene)]-3′,5′-(1‴,3‴-propanediyl)-1′,3′,5′-heptatrienyl-1′-yl}-1-ethyl-3,3-dimethylindoleinine bromide,[99] and upon hydrogen ion-induced changes in absorption spectra of aminodienone-carbocyanine dye system.[100] In the latter example, spectral change resulted from keto–enol tautomerism caused by protonation of oxygen atom. Generally, such spectral changes occur over a fairly narrow pH range of less than 2–3 pH units. Finally several far-VIS and near-infrared spectroscopic probes such as porphines, isoporphines and corroles, as well as select cyclic derivatives of phthalocyanines and naphthalocyanines, have served as complexing agents for metal ions. Specificity of probe for various metal ions in solution is determined by both ring size and analyte's affinity for the lone electron pairs on nitrogen ring atoms. Additional analytical applications will likely result in the next few years. New synthetic procedures are making probe molecules more readily available.

ABBREVIATIONS AND ACRONYMS

BA	9,9′-Bianthracene
BACl	10-Chloro-9,9′-bianthracene
BCECF	Biscarboxyethylcarboxyfluorescein
BCo	Benzo[*a*]coronene
BePy	Benzo[*e*]pyrene
BO	Born–Oppenheimer
BPe	Benzo[*ghi*]perylene
BPP	Benzo[*rst*]pentaphene
BTPHB	2-[4′-Chloro-7′(3″-ethyl-2″-benzothiazolinylidenyl)-3′,5′-(1‴,3‴-propanediyl)-1′,3′,5′-heptatriene-1′-yl]-3-ethylbenzothiazolium bromide
C9A	*N*-(9-Anthryl)carbazole
CD	Cyclodextrin
CF	Carboxyfluorescein
Co	Coronene
CPyB	Cetylpyridinium bromide
CTAB	Cetyltrimethylammonium bromide
DCo	Dibenzo[*a*, *j*]coronene
DHBPe	3,4-Dihydrobenzo[*ghi*]perylene
DiMCF	Dimethylcarboxyfluorescein
DiMeCo	1,2-Dimethylcoronene
ET-30	2,6-Diphenyl-4-(2,4,6-triphenyl-*N*-pyridinio)phenolate
ET-33	2,6-Dichloro-4-(2,4,6-triphenyl-*N*-pyridino)phenolate
GLC	Gas–Liquid Chromatographic
HMCo	7-Hydroxy-4-methylcoumarin
HPLC	High-performance Liquid Chromatography
HT	Herzberg–Teller
LE	Locally Excited
MeCo	Methylcoronene
NCo	Naphtho[2,3*a*]coronene
NK-427	3,3′-Diethyl-2,2′-(4,5 : 4′,5′-dibenzo)-dithiatricarbocyanine iodide
Ov	Ovalene
PAH	Polycyclic Aromatic Hydrocarbon
PANH	Polycyclic Aromatic Nitrogen Heterocycle
PCNMP	4-Phenyl-4-(4-cyano-1-naphthylmethylene)piperidine
PMPAA	*N*-(1-Pyrenylmethyl)-1-pyreneacetamide
PMPBA	*N*-(1-Pyrenylmethyl)-1-pyrenebutamide
PNMP	1-Phenyl-4-(2-naphthylmethylene)-piperidine
PRODAN	6-Propionyl-2-(dimethylamino)-naphthalene
Py	Pyrene
PyDMAP	3-(4′-Dimethylaminophenyl)-1-(1′-pyrenyl)propane
PyPyP	1,3-Bis-(1′-pyrenyl)propane
SDS	Sodium dodecyl sulfate
SNAFL	Seminaphthofluorescein
SNARF	Seminaphthorhodafluor
TBP	2,5,8,11-Tetra-*tert*-butylperylene

TICT	Twisted Intramolecular Charge Transfer
TNS	*p*-Toluidinonaphthalene sulfonate
TTAB	Tetradecyltrimethylammonium bromide
UV	Ultraviolet
VIS	Visible

Circular dichroism (CD) is the difference in absorption, A, of left and right circularly *polarized light, Equation (1):*

$$CD = \Delta A = A_l - A_r \qquad (1)$$

For randomly oriented systems such as solutions of molecules, only chiral molecules will show any CD intensity corresponding to their absorption bands. Chiral molecules are those molecules that cannot be superposed on their mirror images.[1] Chiral *is derived from the Greek word* χειρ *meaning hand, hence the alternate term for chirality, ''handedness''. Two molecules that are mirror images of each other are often referred to as* enantiomers *and equimolar mixtures of two enatiomers form a racemic mixture which has no net CD intensity in solution.*

Linear dichroism (LD) is the difference in absorption of light linearly *polarized parallel and perpendicular to an orientation axis, Equation (68):*

$$LD = A_{\parallel} - A_{\perp} \qquad (68)$$

1 INTRODUCTION TO CIRCULAR DICHROISM

CD is the difference in absorption, A, of left and right *circularly* polarized light, Equation (1):

$$\mathrm{CD} = \Delta A = A_\mathrm{l} - A_\mathrm{r} \qquad (1)$$

For randomly oriented systems such as solutions of molecules, only chiral molecules will show any CD intensity corresponding to their absorption bands. Chiral molecules are those molecules that cannot be superposed on their mirror images.[1] *Chiral* is derived from the Greek word χειρ meaning hand, hence the alternate term for chirality, ''handedness''. Two molecules that are mirror images of each other are often referred to as *enantiomers* and equimolar mixtures of two enatiomers form a racemic mixture which has no net CD intensity in solution (Figure 1).

In order to understand when chirality is important it is helpful to consider the everyday problem of a pair of shoes, a left foot, and a shoe box. The shoes and the foot are chiral and the left foot only fits comfortably into the left shoe, whereas the achiral shoe box cannot distinguish between the two shoes. Chirality is important only where two chiral entities (usually molecules) interact. CD depends only on the asymmetry of the molecular system and so is uniquely sensitive to this aspect of it. As many of the questions we ask about chemical and

Figure 1 Schematic illustration of CD.

biological systems relate to the shapes of molecules and how this affects their properties, CD is a very useful tool for studying chiral molecules.

CD is now a routine tool in many laboratories. The most common applications are determining whether a chiral molecule has been synthesized or resolved into pure enantiomers and probing the structure of biological macromolecules, in particular determining the α-helical content of proteins.

1.1 Circularly Polarized Light

Although in principle CD can be measured for any kind of electromagnetic radiation absorbed by a sample, in practice experiments are usually limited to the visible or the easily accessible ultraviolet (UV) wavelength range (~170–800 nm). We often loosely refer to this electromagnetic radiation as "light". Vibrational circular dichroism (VCD) using infrared radiation is also used, but is technically significantly more challenging.[2] We shall concentrate on the ultraviolet/visible (UV/VIS) CD as this instrumentation is more readily available and significantly more widely used than VCD.

Electromagnetic radiation, as its name implies, has an electric and a magnetic field that oscillate at right angles to one another and to the propagation direction (Figure 2).[3–7] Light may be described by a transverse wave whose *polarization* is defined by the direction of its electric field, **E**. Electromagnetic radiation also has particle character: if we do an experiment that would probe wave-like behavior, it is apparent that light has it, and if we look for particle character we find that too. Thus we refer to the *wavelength*, λ, and *frequency*, ν, of radiation, but acknowledge that if a molecule absorbs energy it absorbs discrete units called *photons* whose energy are given by Planck's relationship,

Figure 2 Schematic illustration of electromagnetic radiation illustrating the electric field, **E**, the magnetic field, **B**, and the propagation direction **k**. (a) Linearly polarized and (b) right circularly polarized electromagnetic radiation. Arrows denote direction of **E**.

Equation (2)[3–7]

$$E = h\nu = \frac{hw}{2\pi} = \hbar w \tag{2}$$

where h is Planck's constant and w is known as the angular frequency. It follows from the wave nature of light that a light beam can be linearly polarized with all photons having their electric field oscillating in the same plane (Figure 2). In a circularly polarized light beam the electric field vector retains constant magnitude

in time but traces out a helix about the propagation direction. Following the optics convention[6,8] we take the end of the electric field vector of right circularly polarized light to form a right-handed helix in space at any instant of time. At each point in space or time, the magnetic field, **B**, is perpendicular to the electric field such that **k**, the propagation direction, **E**, and **B** form a right-handed system as illustrated in Figure 2.

If we take X to be the direction of propagation of the light, then unit vectors describing the polarization (by convention the direction of the electric field component of the light) of two perpendicularly polarized light beams may be written, Equation (3)

$$\hat{\mathbf{e}}_1 = \hat{\mathbf{e}}_Y = (0, 1, 0) \quad \hat{\mathbf{e}}_2 = \hat{\mathbf{e}}_Z = (0, 0, 1) \tag{3}$$

If two equal magnitude beams are combined so that one lags $\pi/2$ or a quarter of a wavelength behind the other, then the electric field vector will trace out a circle giving circularly polarized light. The electric field polarization vector for right circularly polarized light (as defined above) may be written:[6–8]

$$\hat{\mathbf{e}}_\mathrm{r} = \frac{1}{\sqrt{2}} \left\{ (0, 1, -\mathrm{i}) \exp\left(\frac{2\pi \mathrm{i} X}{\lambda} - \mathrm{i}wt \right) \right\} \tag{4}$$

where i is the square root of -1. The oscillation of the electric field vector in time is described by the factor $\exp(-\mathrm{i}wt)$ where w is the angular frequency ($2\pi\nu$) and t is time; the magnitude of the electric field vector remains constant in time, but its direction rotates about X with frequency w. By taking the real part of Equation (4) we see that for an observer sitting at a fixed point, say $X = 0$, the electric field vector of right circularly polarized light rotates in time about X in a clockwise manner. At a fixed time, say $t = 0$, it forms a right-handed helix in space. In what follows we use the polarization vectors:

$$\hat{\mathbf{e}}_\mathrm{l} = \frac{1}{\sqrt{2}}(0, 1, \mathrm{i}) \quad \hat{\mathbf{e}}_\mathrm{r} = \frac{1}{\sqrt{2}}(0, 1, -\mathrm{i}) \tag{5}$$

for, respectively, left and right circularly polarized light, Equation (5).

1.2 Normal Absorption Spectroscopy

Most spectroscopic phenomena arise from the interaction of a molecule with one photon at a time. The molecule either absorbs, emits, or scatters the photon. The simplest form of spectroscopy is absorption, where we measure how much light of a given frequency is absorbed by a collection of molecules. If a molecule absorbs a photon of frequency ν, it increases its energy according to Planck's relationship (Equation 2). Absorbance is defined in terms of the intensity of incident, I_0, and transmitted, I, light, Equation (6):[3–5]

$$A = \log_{10}\left(\frac{I_0}{I} \right. \tag{6}$$

The Beer–Lambert law for the absorption, A, of light by a sample of concentration C is given by Equation (7)[3–5]

$$A = \varepsilon C l \tag{7}$$

where l is the length of the sample through which the light passes and ε is known as the extinction coefficient; if l is measured in cm and C in M (=mol dm^{-3}), then ε has units of mol^{-1} dm^3 cm^{-1}. The Beer–Lambert law is valid as long as the spectrometer can measure I (i.e. the concentration is not so large that essentially all photons are absorbed) and there are no concentration-dependent intermolecular interactions.

In practice, in a collection of molecules, the photons absorbed by different molecules will be of slightly different energies so what we measure is a curve like the absorbance curves of Figure 1, where the signal that is plotted is a measure of the probability that a transition will occur at that energy. Such a plot of the absorbance of light verses λ or ν is known as an *absorption spectrum*.

1.3 Circular Dichroism Spectroscopy

When a molecule absorbs UV and visible light its electronic distribution is altered. Now consider chiral molecules. Because a chiral molecule has no reflection plane, any rearrangement of its electrons will not have one either, so the electrons move in some kind of helix. As the electric field vectors also trace out helices (Figure 1) in circularly polarized light, the interaction between a chiral molecule and left- and right-handed photons will be different. This is the idea behind the definition of CD given in Equation (1). The CD version of the Beer–Lambert law (Equation 7) is Equation (8):

$$\Delta A = (\varepsilon_\mathrm{l} - \varepsilon_\mathrm{r}) C l = (\Delta\varepsilon) C l \tag{8}$$

Thus, a CD spectrum looks similar to an absorbance spectrum in that it occurs at the same wavelengths (Figure 1), but it can be either positive or negative in sign and if more than one transition lie close together, cancellation of intensity may occur (Figure 3). The challenging task is then to relate the helical motions of the electrons to the arrangement of the atoms and bonds in space.

As noted above, a CD spectrum is only expected for solutions of chiral molecules, though achiral molecules oriented skew to a light beam in an oriented sample, such

Figure 3 CD spectra of 0.1 M Λ-$[Co(ethylenediamine)_3]^{3+}$ in a 0.1 cm path length cell and $[Ru(1,10\text{-phenanthroline})_3]^{2+}$. Note cancellation of close lying bands.

as a crystal, will give a signal. The other requirement is that a molecule gives rise to an absorbance signal in the region of interest. If a molecule has no UV/VIS absorbance spectroscopy then no CD signal will be found. Sometimes, as with chiral HPLC (high-performance liquid chromatography) (see below) it is desirable to cause a nonabsorbing molecule to have a CD signal. This may be achieved by derivatizing the analyte molecule with a UV/VIS active chromophore, though care must be taken with the chemistry to ensure inversion of configuration or racemization does not occur.

1.4 Units of Circular Dichroism Spectroscopy

Most CD spectropolarimeters, although they measure differential absorbance, for historical reasons produce a CD spectrum in units of ellipticity, θ, in millidegrees, versus λ, rather than ΔA versus λ. The conversion between these two is given in Equation (9)[6,8]

$$\begin{aligned} \text{CD} = \Delta A(\text{absorbance units}) &= A_\text{l} - A_\text{r} \\ &= \frac{4\pi\theta(\text{degrees})}{180 \ln 10} = \frac{\theta(\text{millidegrees})}{32\,982} \end{aligned} \tag{9}$$

The CD analog of the Beer–Lambert law (Equation 8) then allows conversion to molar absorbance or molar ellipticity. In this context it is important to be clear what concentration is being measured. For example DNA concentrations are often given in terms of bases or phosphates, but may be in terms of base pairs, whereas protein concentrations are commonly in terms of amino acid residues and occasionally whole molecules.

1.5 Optical Activity (Optical Rotation)

Optical rotation (OR) is the difference in refractive indices of left and right circularly polarized light upon passing through the medium, Equation (10):[6]

$$\text{OR} = (n_\text{l} - n_\text{r})\frac{\pi d}{\lambda} \tag{10}$$

the units are radians if λ (wavelength) and d (pathlength) have the same units (usually dm are used). $(n_\text{l} - n_\text{r})$ is called the circular birefringence.

OR is usually measured by determining the rotation of linearly polarized light upon passing through the solution. If the linearly polarized light is rotated clockwise when viewed into the light source the OR is called a positive or right (dextro) OR. OR as a function of λ is called optical rotatory dispersion (ORD). ORD gives an S-shaped curve centered at the CD maximum (the so-called point of anomalous ORD since if a transition has zero band width the ORD would go to plus and minus infinity either side of λ_{max}). The ORD is also nonzero away from an absorption band, hence α_D values (the ORD at the sodium D line, 589 nm) may be used to characterize the enantiomeric excess of a solution (see below). The long-wavelength side of the ORD curve shows a positive ORD contribution for a positive CD band, but a negative ORD for a negative CD band. ORD is sometimes referred to as optical activity.

Since ORD and CD may be written respectively in terms of the dispersive and absorptive parts of the optical activity tensors, with all other factors the same, Kramers–Kronig[6] relations may be used to convert one to the other *if* the complete ORD spectrum or complete CD spectrum is available. The formalism for this process is fairly straightforward; however, in practice the problem is that the ''complete'' spectrum is not available. It is often possible to perform the conversion on a more limited wavelength range with an element of error. Except for single wavelength measurements to quantify enantiomeric excess, ORD is seldom used now as the more direct

relationship between absorbance spectroscopy and CD facilitates the interpretation of data in structural terms.

1.6 Enantiomeric Purity and Enantiomeric Excess

If a CD signal is observed for a solution, then there is a net excess of a chiral analyte; however, unless $\Delta\varepsilon$ for the compound is known, the enantiomeric purity of the sample cannot be determined. Alternative methods that measure the relative amounts of the two enantiomers directly are chiral HPLC[9] and NMR (nuclear magnetic resonance) with chiral shift reagents.[10] Simply choosing a chiral column or mobile phase additive or chiral shift reagent and then performing an experiment which gives only one peak does not prove that the solution is enantiomerically pure. It must be possible to show that if the mixture is racemic (or any percentage mixture of the two enantiomers) that the experimental method does indeed discriminate between the two species.

Enantiomeric purity is often given in terms of the percentage of one enantiomer present. Alternatively, we use enantiomeric excess. Enantiomeric excess relates more directly to the CD signal because if there is no enantiomeric excess then there is no CD signal; conversely the CD observed follows Equation (8) if the solution is enantiomerically pure. Enantiomeric excess is usually defined as the apparent analyte concentration determined from Equation (8) divided by the total analyte concentration, often converted to a percentage, Equation (11)

$$\mathrm{EE}\% = 100 \times \frac{(\text{Concentration of enantiomer 1}) - (\text{Concentration of enantiomer 2})}{(\text{Concentration of enantiomer 1}) + (\text{Concentration of enantiomer 2})} \tag{11}$$

2 STRUCTURE ANALYSIS FROM CIRCULAR DICHROISM

2.1 Introduction

The most obvious result to be deduced from the appearance of a CD spectrum is whether or not there is net asymmetry in the sample. It is not much of an overgeneralization to say that the only CD studies that have been interpreted beyond this stage are those where the transition being studied is essentially located in an achiral chromophore (or electronic subunit) of the system. Explicit calculations can, of course, be performed for intrinsically chiral chromophores (such as CHFClBr), however, this does not usually provide any information except that the input geometry for that molecule is correct. By way of contrast, carbonyl compounds containing the achiral chromophore (circled in Figure 4) have been extensively studied using CD spectroscopy and various structure–spectra correlation rules have been proposed and applied. It should be noted that any structure–spectrum correlation rule can only be applied with full confidence once its mechanistic origin is understood.

Figure 4 Progesterone with the carbonyl chromophores circled. Note progesterone has one carbonyl conjugated with a double bond so it is not strictly electronically independent of the rest of the molecule.

Given that the chromophores we are interested in are achiral, the electron redistribution that occurs during a transition occurs in a plane. This means that either the magnetic dipole transition moment, $\boldsymbol{m}$, (MDTM) (by which the transition interacts with the magnetic field of the radiation) or the electric dipole transition moment, $\boldsymbol{\mu}$, (EDTM) (by which the transition interacts with the electric field of the radiation) vanishes (or they are perpendicular to one another). The $\boldsymbol{m} = 0$, $\boldsymbol{\mu} \neq 0$ transitions are called electric dipole allowed (EDA), magnetic dipole forbidden (MDF). The $\boldsymbol{m} \neq 0$, $\boldsymbol{\mu} = 0$ transitions are called electric dipole forbidden (EDF), magnetic dipole allowed (MDA). The theoretical significance of this division is due to the way CD intensity is induced into the two different types of transitions. EDA transitions require the induction of a magnetic component, whereas MDA transitions require an induced electric component. The dependence of the different kinds of induced moments on the geometry of the system is very different, so when we wish to extract geometric information from CD we must be aware of which situation is in effect. The CD spectrum induced into EDA transitions is also different if it arises from the coupling of identical chromophores rather than from the coupling of nonidentical chromophores.

Experimentally the difference between EDA/MDF and EDF/MDA transitions is that the latter have low absorbance intensity (what they have is usually gained from vibronic coupling rather than from the MDTM) so the ratio of their CD signal to their absorbance is larger than that for EDA/MDF transitions. The dissymmetry factor, g, Equation (12)[6]

$$g = \frac{4R}{cD} \tag{12}$$

where R is the rotational CD strength (Equation 30), c is the speed of light, and D is the dipole strength (square of the EDTM) of the transition summarizes this. The

main historical consequence of this is that most of the early CD experiments were performed on EDF/MDA transitions such as the $n \rightarrow \pi^*$ carbonyl transitions and the T_{1g} tris-chelate transitions.

2.2 Qualitative Description of Circular Dichroism and Its Correlation with Structure for Some Systems

2.2.1 Carbonyl Circular Dichroism

Carbonyl chromophores, i.e. carbonyl functional groups that are not conjugated with any other double bond of the molecule, occur in many organic molecules of both natural and synthetic origin including steroids. That a simple reliable empirical rule relating carbonyl molecular geometry to observed CD spectrum was determined and to some extent rationalized in the 1960s was therefore extremely convenient. The lowest lying transition of a carbonyl is the $n \rightarrow \pi^*$ transition which involves rotation of electron density from the nonbonding oxygen lone pair into the π^* orbital of the C=O bond (Figures 4 and 5). The transition, which occurs somewhere between 350 nm and 240 nm, is weak with an extinction coefficient typically of 20–50 $mol^{-1}\,dm^3\,cm^{-1}$. When it is conjugated with a double bond as in progesterone (Figure 4) the absorbance intensity is increased and any rules to interpret the CD spectra must be applied with care. The octant rule of Moffitt et al.[11] is the unifying feature for much of the carbonyl CD work. In its original form, the rule stated that the CD of the $n \rightarrow \pi^*$ transition depends on the positions of other parts of the molecule relative to the carbonyl group according to Equation (13)

$$-\frac{xyz}{r^n} \tag{13}$$

where (x,y,z) is the unit vector along the lines of the position vector in the right-handed coordinate system of Figure 5 and r is the distance from the centre of the carbonyl bond to the chromophore. Höhn and Weigang[12] used perturbation theory to give a theoretical justification of the octant rule and found that $n = 4$, and that the relative importance of different parts of the molecule scaled with their polarizability. This was the first use of what has come to be called the independent systems/perturbation (ISP) approach.[13–15]

To apply the octant rule to hydrocarbon systems, one simply determines the cartesian coordinates of each carbon atom (assuming the hydrogens make little contribution), evaluates Equation (13) with $n = 4$ and performs a sum over all carbons in the molecule (or in practice over the net perturbers since atoms located symmetrically about a plane of the octant system will give equal magnitude and opposite sign contributions). An example is given in Figure 6. A simple Gaussian type curve with sign and relative magnitude determined by this sum should then correlate with the observed CD. For nonhydrocarbon systems, the sum must be weighted by the polarizabilities of the atoms or chromophores (see below) of the molecule.[16]

Although the octant rule has proved to be highly successful, there are sufficiently numerous exceptions to provide a warning against the blind use of empirical rules. Empirical modifications (see Rodger and Rodger and references therein),[15] while helpful for a given series of compounds, do not provide a global approach. Consideration of all terms in the ISP expansion (see below) is really required. The conclusion from this

Figure 5 (a) Schematic illustration of the carbonyl $n \rightarrow \pi^*$ transition illustrating the (x,y,z) coordinate system used for the octant rule. (b) Octant rule CD signs. Invert the signs illustrated for the $x < 0$ region of space.

Figure 6 Projection onto the x–y octant plane of levonorgestrel butanoate viewed along the carbonyl bond. All atoms (except the carbonyl oxygen) have coordinates with $z < 0$. Octant signs are as indicated. The size of the carbon atoms indicates their proximity to the carbonyl group (large ones are close). The dominant octant rule net perturber lies in the $x < 0, y > 0, z < 0$ octant (although more distant atoms lie in the $x < 0, y < 0, z < 0$ octant) Oxygen atoms are shaded. Thus, a positive $n \rightarrow \pi^*$ CD signal is expected from this molecule. In fact $\Delta\varepsilon_{322\,nm} = 1.5\,mol^{-1}\,dm^3\,cm^{-1}$.[45]

analysis[15] is that the octant rule is not valid for polar and charged groups. It also requires the net perturbing part of the system not to lie on or near one of the octant planes. Further, no solvent cavities must be created by substituents on the molecules and planar zig-zags of bonds with the carbonyl bond must be absent for the CD magnitude to be given by the octant rule.[18]

2.2.2 Transition Metal Complexes

The spectroscopy of transition metal complexes can be subdivided into three categories: in-ligand transitions, which resemble those of the isolated ligands; charge-transfer transitions between the ligand and the metal; and d–d transitions of the chromophore defined by the central metal ion and its directly ligating atoms.

The in-ligand transitions need only be considered for aromatic ligands since they are the only ones for which the CD can be easily measured. This effectively restricts consideration to tris-chelate (and also *cis* bis-chelate) complexes with planar aromatic ligands. The ligands in such molecules are usually of C_{2v} symmetry (Figure 7). The in-ligand CD for these systems can usually be accurately predicted by the Kirkwood–Kuhn coupled oscillator mechanism (see below). As the complexes are based on an octahedral template but themselves have D_3 symmetry, the transitions all occur as couplets of A_2 (z, the three-fold axis, Figure 7) polarized and E_u (x,y) polarized transitions. The coupling of long axis ligand transition moments gives a bisignate CD signal the lower energy component being the out-of-phase E_u component that has a negative sign for the Δ enantiomer[19] and conversely for the Λ enantiomer (see below for the theoretical basis for this conclusion). The A_2 component (in the absence of coupling with other transitions) is equal in magnitude and opposite in sign from the E_u component as illustrated in Figure 3.

Figure 7 $[Ru(1,10\text{-phenanthroline})_3]^{2+}$, a tris-chelate transition metal complex of D_3 symmetry with C_{2v} symmetry planar aromatic ligands. The three-fold (z) axis is out of the plane of the page in the right-hand side of the figure.

Charge transfer CD has also been measured mainly for tris-chelate complexes with planar aromatic ligands. For such molecules the charge transfer bands often obscure the d–d transitions. The lowest energy EDA charge transfer transitions for tris-chelate complexes gives a bisignate signal (E_u/A_2) with the E_u component having the opposite sign from the lowest energy long-axis in-ligand E_u CD (see above). The sign difference can be used to assign the polarization of the charge transfer bands[20] whose energy ordering varies from molecule to molecule, in contrast to the situation for the in-ligand transitions.

Interpreting the CD for the MDA d–d transitions (CD for MDF/EDF is usually very small) is complicated by the fact that the dominant mechanism is determined by the symmetry of the d–d chromophore. One reliable empirical rule has been established over the years for tris-chelate complexes where transitions of E and A_2 polarization occur as close lying couplets: the E band CD signal is larger than the A_2 band signal.[19] The underlying reason for this is that if we take the d–d chromophore to have D_{3d} symmetry (Figure 8) then the E_g band gains its CD intensity from a r^{-4} quadrupolar mechanism (see below), whereas the A_2 band depends on an r^{-6} hexadecapolar mechanism as discussed below. In reality the d–d chromophore of tris-chelate complexes is not achiral but twisted. However, for solution phase work the approximation is satisfactory as the close energy of the A_2 and E components of any band means that any intrinsic CD cancels as it would for the octahedral parent geometry. It is only for crystal CD that the problem is noted.[21]

2.2.3 Macromolecules

The CD of macromolecules[22] differs from that of small molecules in that the spectroscopy of the component

Figure 8 D_{3d} d–d chromophore of $[Co(ethylenediamine)_3]^{3+}$, ethylenediamine = $NH_2CH_2CH_2NH_2$.

parts, such as the amino acids, at least in principle, is usually understood and the form of the CD spectra result largely from the arrangement of the units in space. The CD of macromolecules is most commonly used in one of two ways: (i) to probe changes in the conformation of the macromolecule itself, and (ii) to probe its interaction with small molecules bound to it.

2.2.4 Proteins

At present the main use of CD in the study of proteins is as an empirical guage of protein structure and conformation. Proteins are long chains of amino acids, their primary structure being as illustrated in Figure 9.[23] If the side chain (R_i in Figure 9) is not H, then the ith tetrahedral carbon is a chiral center and we should expect an induced CD signal in transitions of the neighboring amide groups and side chains. If, however, there is free rotation about the bonds of the main chain, the observed amide $n \rightarrow \pi^*$ (occurring at ~220 nm), $\pi \rightarrow \pi^*$ (occurring at 207–190 nm), and $n \rightarrow \sigma^*$ (occurring as a shoulder at 175 nm) CD signals will be small since they will be an average of different geometry factors (see carbonyl CD above and coupled oscillator CD below). Thus a truly random or denatured protein will have only a small CD signal at energies accessible to most CD machines. The most stable conformation of a protein under physiological conditions, however, is not random but composed of well-defined structural units that give macrochiral units with significant CD intensities.

The basis of CD structural analysis of proteins is that the CD spectrum from 250 nm downwards is due largely to transitions of the main backbone chain, so it is independent of the nature of the side chains (this is not always true if there are a large number of well-ordered aromatic side chains or prosthetic groups such as a heme present). In any well-defined structural motif (such as the α-helix where the nth peptide unit forms hydrogen bonds between its C–O and the N–H of the $(n + 4)$th peptide and between its N–H and the $(n - 4)$th C–O; there is a 1.5 Å translation and 100° turn between two consecutive peptide units, giving 3.6 amino acid residues per turn), the chromophores giving rise to the CD are in well-defined positions relative to one another so have a well-defined CD spectrum. The net CD is then the sum of that due to the independent structural units. A wide range of fitting programs for protein CD data are available.[24–26] Some work in terms of the spectra of a set of identified structural

Figure 9 Protein primary structure. R_i denotes the side chain of the ith amino acid.

Figure 10 Typical standard protein motif CD spectra,[26,43] α-helix (—, average of poly(γ-methyl-L-glutamate) in F_6i-PrOH and poly(L-alanine) as a film), antiparallel β-sheet (- - - -, *tert*-butyloxycarbonyl (BOC) (L-alanine)$_7$OMe as a film), parallel β-sheet (– • • –, BOC (L-valine)$_7$OMe as a film), poly(L-proline) II-type helix (• • •, systemin in 10 mM phosphate buffer at 5 °C, pH = 7[43]), and random coil (– • –, collagen at 45 °C in 0.01 M phosphate buffer, pH = 3.5). The CD characteristics of α-helices are a negative signal with separate maxima of similar magnitude at 222 nm (the $n \rightarrow \pi^*$ transition) and 208 nm (part of the $\pi \rightarrow \pi^*$ transition that is polarized parallel to the helix axis); and a positive signal at ~195 nm (part of the $\pi \rightarrow \pi^*$ transition that is polarized perpendicular to the helix axis). The CD characteristics of β-sheets are a negative band at about 220 nm and a positive band of near 200 nm and the CD characteristics of the poly(L-proline) II-type helix are a positive band at ~225 nm and a negative band at about 200 nm.

motifs, others use a basis set of real protein spectra where the percentage of different structural units is known. The approach of Manalavan and Johnson,[25] where a large basis set of such proteins is used and a subset of these randomly chosen until a good fit is obtained probably gives the best estimate of the full range of structural motifs present in proteins. Almost all approaches will give a good α-helix content estimate as its profile is the most distinct and also largest in magnitude as illustrated in Figure 10.

2.2.5 DNA

CD experiments performed on DNAs generally fall into one of two categories: those used to probe the DNA and those used to probe a drug (or other molecule) bound to the DNA. DNA can be viewed as a more-or-less vertical spiral staircase where the steps are made up of pairs of planar aromatic molecules, called base pairs, and the sides are chains of alternating phosphate groups and ribose sugars.[21] The source of the chiral structure in DNA is the sugar backbone which imposes the twisted structure onto the whole molecule. Usually the twist is right-handed, though it appears that left-handed Z-DNA is intrinsically not much less stable than the right-handed forms.[27] The CD of a DNA molecule in the 180–300 nm region is due to the skewed orientation of transitions in the bases. Thus, if the DNA is untwisted there will be less CD and if it is twisted the other way the relative geometries of the coupling transition moments (see below) will change and the CD signal may even invert (as it does for Z-DNA relative to much of the B-DNA spectrum, Figure 11).

2.2.6 Induced Circular Dichroism of a Molecule Bound to DNA

If an achiral molecule is bound to DNA, its transitions gain an induced circular dichroism (ICD) due to perturbation by the chiral DNA. The sign and magnitude of this ICD is crucially dependent on the binding geometry, so in principle should yield information about that binding geometry. At its crudest level the appearance of the CD signal indicates that the drug molecule is bound. If the binding is in a single binding mode or a constant proportion of mixed modes then the ICD signal will be proportional to the concentration of bound drug and a titration series of data can be used to determine the binding constant of the drug to DNA.[8,28] An example is given in Table 1 and Figure 12.

2.3 Interaction of Radiation with Matter and the Rosenfeld Equation for Circular Dichroism

In classical mechanics, the energy of the interaction, H_{int}, between a molecule and the electric, **E**, and magnetic, **B**, fields of electromagnetic radiation is given

Figure 11 CD spectra of (a) —, B-form calf thymus DNA (pH = 6.8, 5 mM NaCl, 1 mM sodium cacodylate); – • – •, B-form poly[d(G–C)]$_2$ (pH = 6.8, 5 mM NaCl, 1 mM sodium cacodylate), and - — -, Z-form poly[d(G–C)]$_2$ (pH = 6.8, 5 mM NaCl, 1 mM sodium cacodylate, 50 μM $[Co(NH_3)_6]^{6+}$) (b) 372 nucleotide A-form mRNA (pH = 7).[44] The CD characteristics of these nucleic acid polymorphs are as follows. B-form: a positive band centered at 275 nm, a negative band at 240 nm, with the zero being around 258 nm. At 220 nm the CD signal either becomes positive or less negative; a small negative peak is then followed by a large positive peak from 180–190 nm. A-form: a positive CD band centered at approximately 260 nm that is larger than the corresponding B-form band, a fairly intense sharp negative band at 210 nm and a very intense positive band at 190 nm. The 250–230 nm region is also usually fairly flat though not necessarily zero. Z-form: a negative CD band at 290 nm, a positive band at approximately 260 nm, a large negative CD signal in the 195–200 nm region, and the CD passes through zero between 180 and 185 nm.

by Equation (14)[3–5,7]

$$H_{\text{int}} = -\boldsymbol{\mu}\mathbf{E} - \boldsymbol{m}\mathbf{B} + \text{higher order multipole terms} \quad (14)$$

where $\boldsymbol{\mu}$ is the electric dipole moment of the molecule and $\boldsymbol{m}$ is its magnetic dipole moment. $\boldsymbol{\mu}$ and $\boldsymbol{m}$ are determined by summing over the electron distribution of the molecule, Equation (15):[3–5,7]

Table 1 Induced CD signals at 215 nm (DNA signal subtracted out) determined for calf thymus DNA with additions of $[Co(NH_3)_6]^{3+}$

Total $[[Co(NH_3)_6]^{3+}](\mu M)$	$ICD_{215} = \rho$ (mdeg)	Concentration of bound ligand, $L_b(\mu M)$
15	1.2	11.4
30	2.13	19.8
50	2.98	27.7
100	3.74	34.7

Path length 1 cm, 100 mM in 10 mM NaCl, 1 mM sodium cacodylate, pH = 7.

Figure 12 (a) Induced spectroscopy method plot[8,28] where $x = \left(\frac{L^k_{tot}}{\rho^k} - \frac{L^j_{tot}}{\rho^j}\right)$ $(\rho^k - \rho^j)$ and $y = L^k_{tot} - L^j_{tot}/(\rho^k - \rho^j)$ for ρ^i the ICD signal for the ith spectrum, and L^i_{tot} the ligand concentration for that spectrum. The intercept equals α, where α relates the bound ligand concentration to the ICD ρ: $L_b = \alpha\rho$, and n is the number of DNA bases per bound ligand. The slope is S_{tot}/α where S_{tot} is the total binding site concentration (i.e. the DNA concentration divided by n). From the graph: $\alpha = 9.3 \pm 1\,\mu M\,mdeg^{-1}$; $n = 16 \pm 2$. (b) Scatchard plot[8,28] using value of α determined from (a). r is binding ratio (concentration of ligand bound divided by DNA base concentration), I_f is the concentration of free ligand. The slope is $-K$, for K the equilibrium binding constant. The binding constant is therefore approximately $100\,000\,M^{-1}$.

$$\boldsymbol{\mu} = e\sum_i (\boldsymbol{r}_i)$$

$$\boldsymbol{m} = \frac{e}{2m_e}\sum_i \{\boldsymbol{r}_i \boldsymbol{p}_i\} \qquad (15)$$

where e is the (negative) unit charge on an electron, $\boldsymbol{r}_i$ denotes the position vector of the ith electron, $\boldsymbol{p}_i$ is the momentum vector for the ith electron, and m_e is the mass of an electron.

When we are interested in spectroscopic phenomena such as absorbance, CD, and LD (see below), we have to move beyond classical mechanics to quantum mechanics since the transitions we study involve discrete amounts of energy, i.e. the energy is quantized. Thus, instead of an expression for the classical energy of the interaction between the radiation and the molecule, we need the interaction Hamiltonian operator.[3–5,7] This follows from Equation (14) by converting $\boldsymbol{\mu}$ and $\boldsymbol{m}$ to operators and the interaction energy to the Hamiltonian operator. Curved 'hats' are used in what follows to denote operators, Equation (16):

$$\hat{H}_{int} = -\hat{\boldsymbol{\mu}}\mathbf{E} - \hat{\boldsymbol{m}}\mathbf{B} + \text{higher order terms} \qquad (16)$$

When we compare the relative strengths of different transitions experimentally we measure the intensity of the transition which is the area under the absorption band. The related theoretical quantity is the probability per unit time, P, that a transition will occur from the initial state, $|i\rangle$, (which is usually the ground state) to the final state, $|f\rangle$:[3–5,7]

$$\begin{aligned} P(|i\rangle \longrightarrow |f\rangle) &= k'|\langle f|\hat{H}_{int}|i\rangle|^2 \\ &= k'\langle f|\hat{H}_{int}|i\rangle^*\langle f|\hat{H}_{int}|i\rangle \\ &= k'\langle i|\hat{H}_{int}|f\rangle\langle f|\hat{H}_{int}|i\rangle \end{aligned} \qquad (17)$$

where the integral is over molecular position coordinates, and k' is a constant. Equation (17) is a form of the Fermi Golden Rule.[3–5,7] It is written in terms of bra–ket notation where the 'bra' $\langle 0|$ state is the complex conjugate of the 'ket' $|0\rangle$. When a bra and a ket are coupled together either directly or either side of an operator, such as $\hat{\boldsymbol{\mu}}$ in Equation (18) below, then we imply that an integral over all space is being performed. Round brackets $|\rangle$ in what follows denote unperturbed states of chromophores A and C (see below), and pointed ones $|\rangle$ denote the states of the whole system. Upon substituting the expression for $\hat{H}_{int}$ into Equation (17) we have Equation (18)

$$\begin{aligned} P(|i\rangle \longrightarrow |f\rangle) = k\{&\langle i|\hat{\boldsymbol{\mu}}|f\rangle\hat{\mathbf{e}}^* + \langle i|\hat{\boldsymbol{m}}|f\rangle\hat{\mathbf{b}}^*\} \\ &\times \{\langle f|\hat{\boldsymbol{\mu}}|i\rangle\hat{\mathbf{e}} + \langle f|\hat{\boldsymbol{m}}|i\rangle\hat{\mathbf{b}}\} \end{aligned} \qquad (18)$$

where $\hat{\mathbf{e}}$ is the unit vector along $\mathbf{E}$, $\hat{\mathbf{b}}$ is the unit vector along $\mathbf{B}$, the asterisk denotes the complex conjugate, $|i\rangle^* = \langle i|$, and the magnitudes of the electric and magnetic fields are absorbed into the constant k. $\langle f|\hat{\boldsymbol{\mu}}|i\rangle$ is the EDTM *from* state i *to* state f, and $\langle f|\hat{\boldsymbol{m}}|i\rangle$ the corresponding MDTM.

It follows that,[8] Equation (19)

$$P(|i\rangle \longrightarrow |f\rangle) = k[\boldsymbol{\mu}^{fi}\hat{\mathbf{e}}^*\boldsymbol{\mu}^{if}\hat{\mathbf{e}} + \boldsymbol{m}^{fi}\hat{\mathbf{b}}^*\boldsymbol{m}^{if}\hat{\mathbf{b}}]_{(\mathrm{I})} + k[\boldsymbol{\mu}^{if}\hat{\mathbf{e}}\boldsymbol{m}^{fi}\hat{\mathbf{b}}^* + \boldsymbol{\mu}^{fi}\hat{\mathbf{e}}^*\boldsymbol{m}^{if}\hat{\mathbf{b}}]_{(\mathrm{II})} \quad (19)$$

where $\boldsymbol{\mu}^{if} = \boldsymbol{\mu}^{i\to f} = \langle f|\hat{\boldsymbol{\mu}}|i\rangle$ and so on (note inversion of order of states in the notation).

2.3.1 *Interaction of a Molecule with Linearly Polarized Light: Absorbance and Linear Dichroism*

If no external magnetic field is present (except that due to the radiation) we can choose $|i\rangle$ and $|f\rangle$ to be real wavefunctions; thus $\boldsymbol{\mu}^{fi} = \boldsymbol{\mu}^{if}$ but $\boldsymbol{m}^{fi} = -\boldsymbol{m}^{if}$ since $\hat{\boldsymbol{m}}$ is imaginary. The polarization vectors for **E**, and hence **B**, are also real for linearly polarized light. It follows that the two parts of term (II) in Equation (19) are equal in magnitude but opposite in sign, so term II is zero. As magnetic terms are invariably small compared with electric ones, we can ignore the second term within term (I) and therefore write the probability of the transition occurring from $|i\rangle$ to $|f\rangle$ with light polarized parallel to the electric field (the absorbance, A_e, of the transition) to be:

$$A_\mathrm{e}(|i\rangle \longrightarrow |f\rangle) = k|\boldsymbol{\mu}^{if}\hat{\mathbf{e}}|^2 \quad (20)$$

For the usual situation where the system is a collection of randomly oriented molecules, the interaction averages to $\frac{1}{3}$ Equation (20) and becomes Equation (21):[3–5]

$$A_\mathrm{iso} = A = \frac{k}{3}|\boldsymbol{\mu}^{if}|^2 \quad (21)$$

where A_iso is the isotropic absorbance. LD, which forms the subject matter of the next section, is the difference in absorption of two in-phase linearly polarized light beams propagating in the same direction with perpendicular polarizations. Take the (‖) direction to be (0,0,1) and the perpendicular direction to be (0,1,0). Then Equation (22) follows from Equation (20)

$$\mathrm{LD}_\mathrm{molecule} = (A_\parallel - A_\perp)_\mathrm{molecule} = k\{|\mu_Z^{if}|^2 - |\mu_Y^{if}|^2\} \quad (22)$$

where μ_Y^{if} is the Y component of the $|i\rangle$ to $|f\rangle$ transition dipole moment, and so on. For a collection of N molecules we sum over the LD for each molecule, Equation (23)

$$\mathrm{LD}_\mathrm{total} = \sum_\mathrm{molecules}(A_\parallel - A_\perp)_\mathrm{molecule} = Nk\{\langle|\mu_Z^{if}|^2\rangle - \langle|\mu_Y^{if}|^2\rangle\} \quad (23)$$

where $\langle\rangle$ denotes average. The net LD thus depends on the method and extent of sample orientation since $\{X, Y, Z\}$ is a laboratory-fixed axis system about which the molecule knows nothing unless we tell it. In the absence of any molecular orientation the LD in Equation (23) vanishes because all molecular axes are equally likely to coincide with Z so, Equation (24)

$$\langle|\mu_Z^{if}|^2\rangle = \langle|\mu_Y^{if}|^2\rangle = \tfrac{1}{3}|\boldsymbol{\mu}^{if}|^2 \quad (24)$$

2.3.2 *Interaction of a Molecule with Circularly Polarized Light: Circular Dichroism*

When the radiation is circularly polarized, CD becomes possible. As long as there is no magnetic field (apart from that of the radiation) present, we can again choose to use real wavefunctions so $\boldsymbol{\mu}^{fi} = \boldsymbol{\mu}^{if}$ and $\boldsymbol{m}^{fi} = -\boldsymbol{m}^{if}$. To evaluate Equation (1) we substitute first the expression for left circularly polarized light into Equation (19) then subtract from it the result of substituting the expression for right circularly polarized light. We also make use of the equality $\hat{\mathbf{e}}_\mathrm{r} = \hat{\mathbf{e}}_\mathrm{l}^*$, and note that,[6–8] Equations (25) and (26)

$$\hat{\mathbf{b}} = \mathbf{k}\hat{\mathbf{e}} \quad (25)$$

so

$$\hat{\mathbf{b}}_\mathrm{l} = \tfrac{1}{\sqrt{2}}(1,0,0)\,(0,1,\mathrm{i}) = \tfrac{1}{\sqrt{2}}(0,-\mathrm{i},1) = \hat{\mathbf{b}}_\mathrm{r}^* \quad (26)$$

Thus[8]

$$\mathrm{CD} = A_\mathrm{l} - A_\mathrm{r} = k\underbrace{(\boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}^*\boldsymbol{\mu}^{if}\hat{\mathbf{e}}_\mathrm{l} + \boldsymbol{m}^{fi}\hat{\mathbf{b}}_\mathrm{l}^*\boldsymbol{m}^{if}\hat{\mathbf{b}}_\mathrm{l}) - (\boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}\boldsymbol{\mu}^{if}\hat{\mathbf{e}}_\mathrm{l}^* + \boldsymbol{m}^{fi}\hat{\mathbf{b}}_\mathrm{l}\boldsymbol{m}^{if}\hat{\mathbf{b}}_\mathrm{l}^*)}_{(\mathrm{I})} + k\underbrace{(\boldsymbol{\mu}^{if}\hat{\mathbf{e}}_\mathrm{l}\boldsymbol{m}^{fi}\hat{\mathbf{b}}_\mathrm{l}^* + \boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}^*\boldsymbol{m}^{if}\hat{\mathbf{b}}_\mathrm{l}) - (\boldsymbol{\mu}^{if}\hat{\mathbf{e}}_\mathrm{l}^*\boldsymbol{m}^{fi}\hat{\mathbf{b}}_\mathrm{l} + \boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}\boldsymbol{m}^{if}\hat{\mathbf{b}}_\mathrm{l}^*)}_{(\mathrm{II})} \quad (27)$$

Because $\boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}^*\boldsymbol{\mu}^{if}\hat{\mathbf{e}}_\mathrm{l} = \boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}\boldsymbol{\mu}^{if}\hat{\mathbf{e}}_\mathrm{l}^*$ and so on (the wavefunctions are real), the term (I) vanishes. Upon rearranging term (II) so that the EDTMs are all from $|f\rangle$ to $|i\rangle$ and the magnetic moments are the reverse, Equation (27) becomes Equation (28)[8]

$$\mathrm{CD} = A_\mathrm{l} - A_\mathrm{r} = 2k[\boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}^*\boldsymbol{m}^{if}\hat{\mathbf{b}}_\mathrm{l} - \boldsymbol{\mu}^{fi}\hat{\mathbf{e}}_\mathrm{l}\boldsymbol{m}^{if}\hat{\mathbf{b}}_\mathrm{l}^*] \quad (28)$$

Substitution of explicit forms for the electric and magnetic field (Equations 5 and 25) polarizations for the circularly polarized radiation, gives Equation (29)[8]

$$\mathrm{CD} = -2\mathrm{i}k[\mu_Y^{fi}m_Y^{if} + \mu_Z^{fi}m_Z^{if}] = 2k\mathrm{Im}[\mu_Y^{fi}m_Y^{if} + \mu_Z^{fi}m_Z^{if}] \quad (29)$$

where 'Im' denotes 'the imaginary part of'.

CD experiments are usually performed on collections of randomly oriented molecules. In that case the laboratory (radiation) defined axis system does not relate in any fixed way to a molecular axis system, so what

is measured is a rotational average of Equation (29) in Equation (30a):

$$\mathrm{CD} = \tfrac{4}{3}k\langle i|\tilde{\boldsymbol{\mu}}|f\rangle\langle f|\tilde{\boldsymbol{m}}|i\rangle = \tfrac{4}{3}k\mathrm{Im}[\boldsymbol{\mu}^{fi}\boldsymbol{m}^{if}] \qquad (30a)$$

The CD for the transition *from* state $|i\rangle$ *to* state $|f\rangle$ is thus given by the Rosenfeld equation (Equation 30b):[29]

$$\mathrm{CD} = \mathrm{Im}[\boldsymbol{\mu}^{fi}\boldsymbol{m}^{if}] \qquad (30b)$$

Recall that $\boldsymbol{\mu}^{fi}$ is the EDTM from state $|f\rangle$ to state $|i\rangle$.

If we limit our consideration to achiral molecules but impose an external magnetic field, then term (II) of Equation (27) vanishes, but term (I) does not (the states are complex rather than real). Further, we ignore the terms that involve squares of MDTMs as they will be much smaller than any EDTM terms. The magnetic circular dichroism (MCD) may then be written as Equation (31)

$$\begin{aligned}\mathrm{MCD} &= k[(\mu_X^{fi} - \mathrm{i}\mu_Z^{fi})(\mu_Y^{if} + \mathrm{i}\mu_Z^{if}) - (\mu_Y^{fi} + \mathrm{i}\mu_Z^{fi})(\mu_Y^{if} + \mathrm{i}\mu_Z^{if})] \\ &= 2\mathrm{i}k(\mu_Y^{fi}\mu_Z^{if} - \mu_Z^{fi}\mu_Y^{if}) \qquad (31)\end{aligned}$$

We shall not deal further with MCD in this article. See Rodger and Nordén[8,31] for more details.

2.4 Circular Dichroism of Magnetic Dipole Allowed Transitions: Why the Octant Rule Works for Carbonyls

In this section and the next we shall be working within the chromophoric or independent systems/perturbation (ISP) approach to CD theory,[8,12,13,15] and will limit our consideration to transitions in achiral chromophores, A, that acquire CD intensity by coupling to transitions in other chromophores C. C need not itself be chiral but it must be positioned so that {A + C} forms a chiral system. A *chromophore* is strictly a part of a system whose wavefunctions have *no* overlap with the rest of the system; electronic wavefunctions in a chromophore therefore have no electron exchange with the rest of the system. In practice, a chromophore is usually identified for a given electronic transition if that transition seems to be more or less dependent on only the identity of a subset of the molecule (such as the carbonyl functional group).

We also need to be able to write an equation for the interaction between A and C. Since there is no electron exchange between A and C (by definition), their interaction, V, is purely coulombic, Equation (32)

$$V = \sum_{a,c} \frac{q_\mathrm{a}q_\mathrm{c}}{|\boldsymbol{R}_\mathrm{AC} + \boldsymbol{r}_\mathrm{c} - \boldsymbol{r}_\mathrm{a}|} \qquad (32)$$

where q_a is the charge of a particle in A located at the end of the vector, $\boldsymbol{r}_\mathrm{a}$, that begins at the A origin, similarly q_c and $\boldsymbol{r}_\mathrm{c}$, and $\boldsymbol{R}_\mathrm{AC} = \boldsymbol{R}_\mathrm{C} - \boldsymbol{R}_\mathrm{A}$ is the vector from the origin of chromophore A to the origin of chromophore C (Figure 13).

Figure 13 A and C chromophores.

The electric dipole moment operator, $\tilde{\boldsymbol{\mu}}$, where $\tilde{}$ is used here to indicate an operator for the whole system, may be written in terms of A and C operators as, Equation (33)

$$\tilde{\boldsymbol{\mu}} = e\left\{\sum_a(\hat{\boldsymbol{R}}_\mathrm{A} + \hat{\boldsymbol{r}}_\mathrm{a}) + \sum_c(\hat{\boldsymbol{R}}_\mathrm{C} + \hat{\boldsymbol{r}}_\mathrm{c})\right\} \qquad (33)$$

where $\hat{\boldsymbol{R}}_\mathrm{A} = \boldsymbol{R}_\mathrm{A}$ is the position operator for the A origin in the global coordinate system, and $\hat{\boldsymbol{r}}_\mathrm{a} = \boldsymbol{r}_\mathrm{a}$ is the position operator within A for particle a (Figure 13). We shall be considering only transition moments, so since $\boldsymbol{R}_\mathrm{A}$ is constant it follows that[8]

$$\tilde{\boldsymbol{\mu}} = e\left\{\sum_a(\hat{\boldsymbol{r}}_\mathrm{a}) + \sum_c(\hat{\boldsymbol{r}}_\mathrm{c})\right\} = \hat{\boldsymbol{\mu}}_\mathrm{A} + \hat{\boldsymbol{\mu}}_\mathrm{C} \qquad (34)$$

where $\hat{\boldsymbol{\mu}}_\mathrm{A}$ is the electric dipole moment operator for A and operates only on wavefunctions of A.

Similarly it follows from Equation (15) that the magnetic dipole moment operator for the whole system is,[8] Equation (35)

$$\begin{aligned}\tilde{\boldsymbol{m}} &= \breve{\boldsymbol{m}}_\mathrm{A} + \breve{\boldsymbol{m}}_\mathrm{C} \\ &= \frac{e}{2m_\mathrm{e}}\left\{\sum_a(\hat{\boldsymbol{R}}_\mathrm{A} + \hat{\boldsymbol{r}}_\mathrm{a})\hat{\boldsymbol{p}}_\mathrm{a} + \sum_c(\hat{\boldsymbol{R}}_\mathrm{C} + \hat{\boldsymbol{r}}_\mathrm{c})\hat{\boldsymbol{p}}_\mathrm{c}\right\} \\ &= \frac{e}{2m_\mathrm{e}}\hat{\boldsymbol{R}}_\mathrm{A}\sum_a\hat{\boldsymbol{p}}_\mathrm{a} + \hat{\boldsymbol{m}}_\mathrm{A} + \frac{e}{2m_\mathrm{e}}\hat{\boldsymbol{R}}_\mathrm{C}\sum_c\hat{\boldsymbol{p}}_\mathrm{c} + \hat{\boldsymbol{m}}_\mathrm{C} \\ &= \frac{e}{2m_\mathrm{e}}\hat{\boldsymbol{R}}_\mathrm{A}\hat{\boldsymbol{p}}_\mathrm{A} + \hat{\boldsymbol{m}}_\mathrm{A} + \frac{e}{2m_\mathrm{e}}\hat{\boldsymbol{R}}_\mathrm{C}\hat{\boldsymbol{p}}_\mathrm{C} + \hat{\boldsymbol{m}}_\mathrm{C} \qquad (35)\end{aligned}$$

where $\hat{\boldsymbol{m}}_\mathrm{A}$ is the total magnetic moment for chromophore A, $\hat{\boldsymbol{p}}_\mathrm{A}$ is the linear momentum operator for chromophore A, $\hat{\boldsymbol{m}}_\mathrm{A}$ is the intrinsic magnetic dipole moment operator within A, and so on. Thus the total magnetic moment for A includes both the intrinsic magnetic moment operator within the chromophore and any magnetic moment due to the linear motion of its charges about the system origin.

To evaluate the Rosenfeld equation (Equation 30b) for two interacting chromophores we need to know $\boldsymbol{\mu}^{01}$ and $\boldsymbol{m}^{01}$ for the whole system, i.e. for the $|0\rangle \rightarrow |1\rangle$ transition, which is the $|0) \rightarrow |1)$ transition on A in the presence of any perturbation due to C. We write the wavefunctions for the A/C system when their interaction is switched off as the product wavefunctions $|a)|c) = |ac)$ where $|a)$ is a wavefunction of A and $|c)$ is a wavefunction of C. The A function is always written first even in the ket form, thus, Equation (36)

$$\{|a)|c)\}^* = \{|ac)\}^* = (a|(c| = (ac| \tag{36}$$

A operators only operate on A wavefunctions, similarly C operators only operate on C wavefunctions. For example, Equation (37)

$$(a'c'|\widehat{\boldsymbol{\mu}}_{\mathrm{A}}|ac) = (a'|\widehat{\boldsymbol{\mu}}_{\mathrm{A}}|a)(c'|c) = \boldsymbol{\mu}_{\mathrm{A}}^{aa'}\delta_{cc'} \tag{37}$$

where $\delta_{cc'} = 0$ unless $c' = c$.

We are considering the situation when the $|0) \rightarrow |1)$ transition of A is MDA and EDF so $\boldsymbol{m}_{\mathrm{A}}^{01} \neq 0$ but $\boldsymbol{\mu}_{\mathrm{A}}^{10} = 0$. An EDF transition of an achiral chromophore, A, must 'borrow' some electric character in order to have a CD signal. If we also assume that *transition* moments give significantly stronger effects than *permanent* moments, then the 'dynamic coupling' model for the CD of MDA transitions follows.[12] Historically much more effort has been put into what is known as the 'static coupling' or 'one electron' mechanism (since one electron on A is assumed to be the only one to move) where the molecular framework provides a static perturbation via permanent moments. This mechanism certainly contributes to the net observed CD, however, its contribution is almost always smaller than that due to the dynamic coupling mechanism. More details about the static coupling model may be found in references in Schellman.[31]

To determine the wavefunctions of the interacting A/C system we first consider an A/C system where A and C do not interact. The Hamiltonian, $\widehat{H}$, of the noninteracting system is the sum, Equation (38)

$$\widehat{H} = \widehat{H}_{\mathrm{A}} + \widehat{H}_{\mathrm{C}} \tag{38}$$

where $\widehat{H}_{\mathrm{A}}$ is the Hamiltonian of isolated A, and similarly $\widehat{H}_{\mathrm{C}}$. This Hamiltonian is separable and the total energy of a state $|ac)$ is the energy of $|a)$ in A plus that of $|c)$ in C. So, for example, $|01)$ means A is in its ground state and C is in state $|1)$. The energy of the $|01)$ state of the combined system is therefore $0 + \varepsilon = \varepsilon$ (taking the zero point of energy to be when both A and C are in their ground states).

When the electrostatic interaction, V (Equation 32), is 'switched' on between A and C then the Hamiltonian of the interacting system is, Equation (39)

$$\widehat{H} = \widehat{H}_{\mathrm{A}} + \widehat{H}_{\mathrm{C}} + V \tag{39}$$

The wavefunctions for the combined system could be determined using the Equation (32) expression for V and the variation principle. We shall use perturbation theory to give expressions for the wavefunctions and later assume that A and C are far enough apart to expand V as a double Taylor series expansion to give terms dependent on monopoles, dipoles, quadrupoles and so on of A and C. This approach has the disadvantage of giving different final equations for degenerate and nondegenerate systems (and ignores near degenerate systems); however, it has the advantage of enabling us to write equations that can be used to relate system geometry to CD signal.

The perturbed wavefunctions $|i\rangle = |00\rangle$ and $|f\rangle = |10\rangle$ for the MDTM case where the perturbation comes from EDTMs are determined from nondegenerate perturbation theory to first order in V Equations (40) and (41):[3–5,32]

$$|00\rangle = |00) - \frac{(1c|V|00)}{\varepsilon_{\mathrm{c}} + \varepsilon_{\mathrm{a}}}|1c) \tag{40}$$

$$|10\rangle = |10) - \frac{(oc|V|10)}{\varepsilon_{\mathrm{c}} - \varepsilon_{\mathrm{a}}}|0c) \tag{41}$$

from which it follows that, Equation (42)

$$\begin{aligned}\boldsymbol{\mu}^{10} &= \langle 00|\tilde{\boldsymbol{\mu}}|10\rangle = \langle 00|\widehat{\boldsymbol{\mu}}_{\mathrm{A}} + \widehat{\boldsymbol{\mu}}_{\mathrm{C}}|10\rangle \\ &= (00|\widehat{\boldsymbol{\mu}}_{\mathrm{A}}|10) - \frac{(00|V|1c)}{\varepsilon_{\mathrm{c}} + \varepsilon_{\mathrm{a}}}(1c|\widehat{\boldsymbol{\mu}}_{\mathrm{C}}|10) \\ &\quad - \frac{(0c|V|10)}{\varepsilon_{\mathrm{c}} - \varepsilon_{\mathrm{a}}}(00|\widehat{\boldsymbol{\mu}}_{\mathrm{C}}|0c) \\ &= -\frac{(00|V|1c)}{\varepsilon_{\mathrm{a}} + \varepsilon_{\mathrm{c}}}\widehat{\boldsymbol{\mu}}_{\mathrm{C}}^{0c} - \frac{(0c|V|10)}{\varepsilon_{\mathrm{c}} - \varepsilon_{\mathrm{a}}}\widehat{\boldsymbol{\mu}}_{\mathrm{C}}^{c0} = -\frac{2\varepsilon_{\mathrm{c}}V^{1c}}{\varepsilon_{\mathrm{c}}^2 - \varepsilon_{\mathrm{a}}^2}\widehat{\boldsymbol{\mu}}_{\mathrm{C}}^{c0}\end{aligned} \tag{42}$$

since the A and C wavefunction are real. Similarly, Equation (43)

$$\begin{aligned}\boldsymbol{m}^{01} &= \langle 10|\tilde{\boldsymbol{m}}|00\rangle = \langle 10|\widehat{\boldsymbol{m}}_{\mathrm{A}} + \widehat{\boldsymbol{m}}_{\mathrm{C}}|00\rangle \\ &= (10|\widehat{\boldsymbol{m}}_{\mathrm{A}}|00) - \frac{(1c|V|00)}{\varepsilon_{\mathrm{a}} + \varepsilon_{\mathrm{c}}}(10|\widehat{\boldsymbol{m}}_{\mathrm{C}}|1c) \\ &\quad - \frac{(10|V|0c)}{\varepsilon_{\mathrm{c}} - \varepsilon_{\mathrm{a}}}(0c|\widehat{\boldsymbol{m}}_{\mathrm{C}}|00) \\ &= \boldsymbol{m}_{\mathrm{A}}^{01} - \frac{(1c|V|00)}{\varepsilon_{\mathrm{a}} + \varepsilon_{\mathrm{c}}}\boldsymbol{m}_{\mathrm{C}}^{c0} - \frac{(10|V|0c)}{\varepsilon_{\mathrm{c}} - \varepsilon_{\mathrm{a}}}\boldsymbol{m}_{\mathrm{C}}^{0c} \\ &= \boldsymbol{m}_{\mathrm{A}}^{01} - \frac{2\varepsilon_{\mathrm{a}}V^{1c}}{\varepsilon_{\mathrm{c}}^2 - \varepsilon_{\mathrm{a}}^2}\boldsymbol{m}_{\mathrm{C}}^{0c}\end{aligned} \tag{43}$$

Substitution into the Rosenfeld equation (Equation 30b) gives the so-called dynamic coupling CD expressions to first order in V,[14,33] Equation (44)

$$R = \mathrm{Im}\left\{\frac{-2\varepsilon_c V^{1c}}{\varepsilon_c^2 - \varepsilon_a^2}\boldsymbol{\mu}_C^{c0}\boldsymbol{m}_A^{01}\right\} \tag{44}$$

The above equations are for systems composed of A plus one C. If there are two or more Cs then a sum over Cs is introduced.

In order to apply Equation (44) we need to have explicit forms for V^{1c} in terms of electric transition moments of A and C. It is now convenient to use a general form for the terms in the expansion of V using $i, j, k = \{x, y, z\}$ and the Kronecker delta, $\delta_{i,j}$, which is zero unless $i = j$. The dipole–dipole term in the expansion of V is[20] given in Equation (45)

$$\begin{aligned} V^{1c}(\boldsymbol{\mu}_A - \boldsymbol{\mu}_C) = V^{10,0c} &= (0c|V|10) \\ &= \frac{\boldsymbol{\mu}_A^{10}\boldsymbol{\mu}_C^{0c} - 3\widehat{\boldsymbol{R}}_{AC}\boldsymbol{\mu}_A^{10}\boldsymbol{\mu}_C^{0c}\widehat{\boldsymbol{R}}_{AC}}{R_{AC}^3} \\ &= \frac{1}{R_{AC}^3}(\mu_A^{10})_i(\mu_C^{0c})_j[\delta_{ij} - 3(\widehat{R}_{AC})_i(\widehat{R}_{AC})_j] \end{aligned} \tag{45}$$

where a sum over all repeated indices is implied. When substituted into Equation (44) the dipole–dipole term of V leads to a CD expression containing a $(\mu_A^{01})_i(m_A^{10})_k$ term. This moment product vanishes except for chromophores of C_s symmetry (i.e. those with only one reflection plane and no rotation axes) and x- and y- polarized transitions of C_{2v} chromophores. An MDA transition in such a chromophore is also EDA so the CD will probably be dominated by the coupled-oscillator CD of the EDTM which is dependent on $(R_{AC})^{-2}$ (see below).

For magnetically z-polarized transitions in A chromophores of C_{2v} symmetry such as the $n \rightarrow \pi^*$ transition of carbonyls (see above) the quadrupole–dipole term of V is the first nonvanishing one, Equation (46):[14]

$$\begin{aligned} V^{1c}(\boldsymbol{Q}_A - \boldsymbol{\mu}_C) = \frac{3}{2R_{AC}^4}&[(Q_A^{10})_{ij}(\mu_C^{0c})_k] \\ &\times \begin{array}{c}\delta_{ij}(\widehat{R}_{AC})_k + \delta_{ik}(\widehat{R}_{AC})_j + \delta_{jk}(\widehat{R}_{AC})_i \\ -5(\widehat{R}_{AC})_i(\widehat{R}_{AC})_j(\widehat{R}_{AC})_k\end{array} \end{aligned} \tag{46}$$

where $\bar{\boldsymbol{Q}}_A$ is the electric quadrupole moment operator of A. It is a second rank tensor whose components are, Equation (47)

$$(\bar{\boldsymbol{Q}}_A)_{ij} = e\sum_a (\boldsymbol{r}_i\boldsymbol{r}_j) \tag{47}$$

(cf. Equation 15 for notation). The quadrupole–dipole CD term is thus given by Equation (48)

$$\begin{aligned} R = -\frac{3}{R_{AC}^4}\mathrm{Im}&[(Q_A^{10})_{ij}(m_A^{01})_l] \quad \frac{\varepsilon_c(\mu_C^{c0})_l(\mu_C^{0c})_k}{(\varepsilon_c^2 - \varepsilon_a^2)} \\ &\times \begin{array}{c}\delta_{ij}(\widehat{R}_{AC})_k + \delta_{ik}(\widehat{R}_{AC})_j + \delta_{jk}(\widehat{R}_{AC})_i \\ -5(\widehat{R}_{AC})_i(\widehat{R}_{AC})_j(\widehat{R}_{AC})_k\end{array} \end{aligned} \tag{48}$$

Unless $\{i, j\}$ equals $\{x, y\}$ or $\{y, x\}$ the A-moment product (first square brackets in Equation 48) vanishes. Thus the CD strength for MDA z-polarized transitions of C_{2v} chromophores such as the $n \rightarrow \pi^*$ transition of carbonyls (Figure 4) is, Equation (49):[15]

$$\begin{aligned} R(C_{2v}, z) = -\frac{6}{R_{AC}^4}\mathrm{Im}&\quad (Q_A^{01})_{xy}(m_A^{10})_z \quad \frac{\varepsilon_c(\mu_C^{0c})_z}{(\varepsilon_c^2 - \varepsilon_a^2)} \\ &\times \begin{array}{c}(\mu_C^{c0})_x(\widehat{R}_{AC})_y + (\mu_C^{c0})_y(\widehat{R}_{AC})_x \\ -5(\mu_C^{c0})_k(\widehat{R}_{AC})_x(\widehat{R}_{AC})_y(\widehat{R}_{AC})_k\end{array} \end{aligned} \tag{49}$$

The octant rule follows from Equation (49) when we reduced our consideration to the term that has an isotropic polarizability component (the octant rule term), i.e. set $k = z$ and ignore the first two terms in the final brackets. As noted above, there are occasions when the octant rule is not appropriate because other terms in Equation (49) (or even higher order terms in the V expansion) become dominant.

Equation (49) after appropriate symmetry averaging also leads to the CD expressions for degenerately x,y-polarized transitions of molecules with D_{3d} A (Figures 7 and 8), since the A moment product of Equation (49) does not vanish for these polarizations under this symmetry. Take z to be the three-fold rotation axis and x to align with one of the two-fold rotation axes of A. By symmetry, the only nonvanishing A moment products are those in Equation (50) so the E-polarized tris chelate transition metal complex CD is:[20]

$$\begin{aligned} R\left(D_{3d}, \frac{x}{y}\right) = -\mathrm{Im}&\frac{3\varepsilon_c}{4R_{AC}^4(\varepsilon_c^2 - \varepsilon_a^2)} \\ &\begin{array}{c}(Q_A^{10})_{xx}(m_A^{01})_x - (Q_A^{10})_{yy}(m_A^{01})_x \\ -2(Q_A^{10})_{xy}(m_A^{01})_y\end{array} \\ &\times \begin{array}{c}2(\mu_C^{c0})_x(\mu_C^{0c})_x(\widehat{R}_{AC})_x - 5(\mu_C^{c0})_k \\ \times (\mu_C^{0c})_x(\widehat{R}_{AC})_x(\widehat{R}_{AC})_x(\widehat{R}_{AC})_k\end{array} \\ &\times \begin{array}{c}-4(\mu_C^{c0})_x(\mu_C^{0c})_y(\widehat{R}_{AC})_y + 5(\mu_C^{c0})_k \\ \times (\mu_C^{0c})_x(\widehat{R}_{AC})_y(\widehat{R}_{AC})_y(\widehat{R}_{AC})_k\end{array} \\ &\times \begin{array}{c}-2(\mu_C^{c0})_y(\mu_C^{0c})_y(\widehat{R}_{AC})_x + 10(\mu_C^{c0})_k \\ \times (\mu_C^{0c})_x(\widehat{R}_{AC})_x(\widehat{R}_{AC})_y(\widehat{R}_{AC})_k\end{array} \\ &-4[(Q_A^{10})_{yz}(m_A^{01})_x - (Q_A^{10})_{xz}(m_A^{01})_y] \\ &\times \begin{array}{c}(\mu_C^{c0})_y(\mu_C^{0c})_z(\widehat{R}_{AC})_x + 5(\mu_C^{c0})_k \\ \times (\mu_C^{0c})_x(\widehat{R}_{AC})_y(\widehat{R}_{AC})_z(\widehat{R}_{AC})_k\end{array} \\ &\times \begin{array}{c}-(\mu_C^{c0})_z(\mu_C^{0c})_x(\widehat{R}_{AC})_y - 5(\mu_C^{c0})_k \\ \times (\mu_C^{0c})_y(\widehat{R}_{AC})_x(\widehat{R}_{AC})_z(\widehat{R}_{AC})_k\end{array} \\ &\begin{array}{c}+(\mu_C^{c0})_x(\mu_C^{0c})_y(\widehat{R}_{AC})_z - (\mu_C^{c0})_y \\ \times (\mu_C^{0c})_x(\widehat{R}_{AC})_z\end{array} \end{aligned} \tag{50}$$

The isotropic polarizability part of Equation (50) is given in Equation (51)

$$R(D_{3d})_{x,y} = \frac{15\varepsilon_c\alpha_C(\varepsilon_a)}{4R_{AC}^4(\varepsilon_c^2-\varepsilon_a^2)} \quad \mathrm{Im}[(Q_A^{10})_{xx}(m_A^{01})_x - (Q_A^{10})_{yy}(m_A^{01})_x - 2(Q_A^{10})_{xy}(m_A^{01})_y] \times(\widehat{R}_{AC})_x[(\widehat{R}_{AC})_x^2 - 3(\widehat{R}_{AC})_y^2] \tag{51}$$

Equation (51) is the basis of the above discussion of E_g polarized d–d transitions of tris-chelate metal complexes.

When A has higher than two-fold rotational symmetry, then the quadrupole–dipole term of Equation (50) is zero for transitions polarized along the high symmetry rotation axes (e.g. for A_2 polarized transitions of tris-chelates). Since the octupole term in the V expansion also vanishes under these circumstances,[20] the term in the V expansion for A_2 polarized transitions is the hexadecapole–dipole term which has an R_{AC}^{-6} dependence so is smaller than the E_g R_{AC}^{-4} term; hence the dominant E band rule discussed above.

2.5 Circular Dichroism of Electric Dipole Allowed Transitions

For EDA transitions, the independent systems approach leads to mechanisms that are usually referred to as coupled-oscillator models. Because we choose to use perturbation theory to give expressions for wavefunctions (as discussed above), we need to consider identical and nonidentical {A,C} systems separately.

2.5.1 Identical A and C: the Degenerate Coupled Oscillator Model

Most transitions for which we measure UV/VIS absorbance spectra are EDA. If an EDA transition, with EDTM $\boldsymbol{\mu}_A^{01}$ and transition energy ε, of an achiral chromophore, A, has a measurable CD spectrum, then it must have "borrowed" some magnetic character to give a net helical electron rearrangement. The degenerate coupled-oscillator model describes the situation where A and C are identical and the magnetic character comes from the coupling of $\boldsymbol{\mu}_A^{01}$ with the same energy EDTM in C, $\boldsymbol{\mu}_C^{01}$. $\boldsymbol{\mu}_C^{01}$ must be oriented skew relative to $\boldsymbol{\mu}_A^{01}$ for a CD signal to be observed near ε. $\boldsymbol{\mu}_C^{01}$ induces a magnetic effect in A since, although it is a linear motion of charge within C, when viewed from A it moves (circles) around A's origin ($\boldsymbol{\mu}_A^{01}$ simultaneously induces a magnetic component into the C transition $\boldsymbol{\mu}_C^{01}$).

In this case, where A and C are identical, by symmetry (or degenerate perturbation theory) the two states that result from the mixing of $|10\rangle$ (A in $|1\rangle$ and C in the ground state) and $|01\rangle$ are given by Equation (52)[3–5,32]

$$|10_\pm\rangle = \tfrac{1}{\sqrt{2}}\{|10\rangle \pm |01\rangle\} \tag{52}$$

where the $|10_+\rangle$ state takes the upper sign of the $\pm$ or $\mp$ terms in this equation and those that follow. As above, we use real normalized wavefunctions. If we also assume that permanent moments are much smaller than transition moments, then the energies of these two states are, Equation (53)[3–7,32]

$$\begin{aligned}\varepsilon^\pm &= \langle 10_\pm|\widehat{H}_A + \widehat{H}_C \pm V|10_\pm\rangle \\ &= \tfrac{1}{2}\{(10| \pm (01|\}|\widehat{H}_A + \widehat{H}_C + V|\{|10\rangle \pm |01\rangle\} \\ &= \tfrac{1}{2}\{(1|\widehat{H}_A|1) + (0|\widehat{H}_C|0) \pm (10|V|01) \\ &\quad + (0|\widehat{H}_A|0) + (1|\widehat{H}_C|1) \pm (01|V|10)\} \\ &= \varepsilon^0 + \varepsilon^1 \pm V^{10,01} = \varepsilon \pm V^{11}\end{aligned} \tag{53}$$

where, for example, Equation (54)

$$\begin{aligned}V^{ba,dc} &= (ac|V|bd) \\ &= (\boldsymbol{\mu}_A^{ba}\boldsymbol{\mu}_C^{dc} - 3\widehat{\boldsymbol{R}}_{AC}\boldsymbol{\mu}_A^{ba}\boldsymbol{\mu}_C^{dc}\widehat{\boldsymbol{R}}_{AC} \\ &\quad + \text{higher order terms})\, R_{AC}^{-3}\end{aligned} \tag{54}$$

Because all wavefunctions are real, when one state on each of A and C is the ground state we further simplify the notation as indicated in the last line of Equation (53). V^{11} is much smaller than ε so the two new perturbed states are close in energy.

The EDTMs for the transitions from the two excited states of Equation (52) to the ground state $|00\rangle$ are, Equation (55):

$$\begin{aligned}\langle 00|\tilde{\boldsymbol{\mu}}|10_\pm\rangle &= \tfrac{1}{\sqrt{2}}\{(00|\widehat{\boldsymbol{\mu}}_A + \widehat{\boldsymbol{\mu}}_C[|10\rangle \pm |01\rangle]\} \\ &= \tfrac{1}{\sqrt{2}}\{\boldsymbol{\mu}_A^{10} \pm \boldsymbol{\mu}_C^{10}\}\end{aligned} \tag{55}$$

The $|0\rangle \rightarrow |1\rangle$ transitions in both A and C are MDF, and so have no intrinsic magnetic moment. We therefore set $\widehat{\boldsymbol{m}}_A = \widehat{\boldsymbol{m}}_C = 0$ in Equation (35). The momenta MDTM terms are more conveniently dealt with when re-expressed in terms of EDTMs for the appropriate transition exploiting a very useful relationship,[32] Equation (56)

$$(k|\widehat{\boldsymbol{p}}_C|j) = \frac{\mathrm{i}m_e}{e\hbar}(\varepsilon_k - \varepsilon_j)\boldsymbol{\mu}_C^{jk} \tag{56}$$

from which follows Equation (57)

$$\begin{aligned}\boldsymbol{m}_C^{jk} = (k|\tilde{\boldsymbol{m}}_C|j) &= \frac{e}{2m_e}(k|\widehat{\boldsymbol{R}}_C\widehat{\boldsymbol{p}}_C|j) \\ &= \frac{i}{2\hbar}\boldsymbol{R}_C(\varepsilon_k - \varepsilon_j)\boldsymbol{\mu}_C^{jk}\end{aligned} \tag{57}$$

This is the magnetic moment at the origin (0,0,0) created by the tangential EDA transition moment $\boldsymbol{\mu}_C^{jk}$. The

MDTMs for the return transition from to the ground state to the perturbed excited states are then, Equation (58)

$$(10_{\pm}|\tilde{\boldsymbol{m}}|00) = \frac{\mathrm{i}\varepsilon}{\sqrt{8}\hbar}\left\{\boldsymbol{R}_{\mathrm{A}}\mu_{\mathrm{A}}^{01} \pm \boldsymbol{R}_{\mathrm{C}}\mu_{\mathrm{C}}^{01}\right\} \tag{58}$$

Substituting Equations (55) and (58) into the Rosenfeld equation (Equation 30b) gives the CD strengths of bands centered at ε^{+} and ε^{-} (Equation 53) arising from the coupling of degenerate $|0) \rightarrow |1)$ transitions on A and C to be,[8] Equation (59)

$$\begin{aligned} R_{\pm}^{01} &= \pm\frac{\varepsilon}{4\hbar}\left\{\mu_{\mathrm{C}}^{01}\mu_{\mathrm{A}}^{01}(R_{\mathrm{C}} - \boldsymbol{R}_{\mathrm{A}})\right\} \\ &= \pm\frac{\varepsilon}{4\hbar}\left\{\boldsymbol{\mu}_{\mathrm{C}}^{01}\boldsymbol{\mu}_{\mathrm{A}}^{01}\boldsymbol{R}_{\mathrm{AC}}\right\} \end{aligned} \tag{59}$$

where the '+' transition is not necessarily higher in energy than the '−' transition.

The physical interpretation and applications of Equation (59) for solving geometric and spectroscopic problems is most easily seen by choosing the coordinate system illustrated in Figure 14 in which case Equation (59) may be written, Equation (60):

$$R^{\pm} = \pm\frac{\varepsilon\mu^2 R_{\mathrm{AC}}}{4\hbar}\sin\alpha\sin\gamma\sin\tau \tag{60}$$

and the energies of the two bands are, Equation (61)

$$\varepsilon^{\pm} = \varepsilon \pm \frac{\mu^2(\sin\alpha\sin\gamma\cos\tau + 2\cos\alpha\cos\gamma)}{R_{\mathrm{AC}}^3} \tag{61}$$

where μ is the magnitude of μ_{A} and μ_{C}.

The expected CD spectrum for two degenerate chromophores as a function of τ is illustrated in Figure 15. Because independent systems theory is identical to the theory of exciton particles, these degenerate couplets are often referred to as exciton CD spectra.

2.5.2 *Different A and C: Nondegenerate Coupled Oscillator Circular Dichroism*

When A and C are not identical then the wavefunctions of the A/C system follow from nondegenerate perturbation theory.[3–5,32] We may write Equations (62) and (63)

$$|00\rangle = |00) - \frac{(1c|V|00)}{\varepsilon_{\mathrm{c}} + \varepsilon_{\mathrm{a}}}|1c) \tag{62}$$

$$|10\rangle = |10) - \frac{(0c|V|10)}{\varepsilon_{\mathrm{c}} - \varepsilon_{\mathrm{a}}}|0c) \tag{63}$$

The EDTM of the perturbed $|10\rangle \rightarrow |00\rangle$ transition is given by Equation (64)

$$\begin{aligned} \boldsymbol{\mu}^{10} &= \langle 00|\tilde{\boldsymbol{\mu}}|10\rangle = \langle 00|\hat{\boldsymbol{\mu}}_{\mathrm{A}} + \hat{\boldsymbol{\mu}}_{\mathrm{C}}|10\rangle \\ &= (00|\hat{\boldsymbol{\mu}}_{\mathrm{A}}|10) - (00|\hat{\boldsymbol{\mu}}_{\mathrm{C}}|0c)\frac{(0c|V|10)}{\varepsilon_{\mathrm{c}} - \varepsilon_{\mathrm{a}}} \\ &\quad - (1c|\hat{\boldsymbol{\mu}}_{\mathrm{C}}|10)\frac{(00|V|1c)}{\varepsilon_{\mathrm{c}} + \varepsilon_{\mathrm{a}}} = \boldsymbol{\mu}_{\mathrm{A}}^{10} - \frac{2\varepsilon_{\mathrm{c}}V^{1c}}{\varepsilon_{\mathrm{c}}^2 - \varepsilon_{\mathrm{a}}^2}\boldsymbol{\mu}_{\mathrm{C}}^{c0} \end{aligned} \tag{64}$$

Similarly,[8] Equation (65)

$$\begin{aligned} \boldsymbol{m}^{01} &= \langle 10|\tilde{\boldsymbol{m}}|00\rangle = \frac{e}{2m_{\mathrm{e}}}\left\{\boldsymbol{R}_{\mathrm{A}}\boldsymbol{p}_{\mathrm{A}}^{01} - \frac{2\varepsilon_{\mathrm{a}}V^{1c}}{\varepsilon_{\mathrm{c}}^2 - \varepsilon_{\mathrm{a}}^2}\boldsymbol{R}_{\mathrm{C}}\boldsymbol{p}_{\mathrm{C}}^{0c}\right\} \\ &= \frac{\mathrm{i}}{2\hbar}\left\{\varepsilon_{\mathrm{a}}\boldsymbol{R}_{\mathrm{A}}\boldsymbol{\mu}_{\mathrm{A}}^{01} - \frac{2\varepsilon_{\mathrm{a}}\varepsilon_{\mathrm{c}}V^{1c}}{\varepsilon_{\mathrm{c}}^2 - \varepsilon_{\mathrm{a}}^2}\boldsymbol{R}_{\mathrm{C}}\boldsymbol{\mu}_{\mathrm{C}}^{0c}\right\} \end{aligned} \tag{65}$$

since the transition has no intrinsic magnetic moment within A as in the case of the degenerate coupled oscillator model.

The CD strength is therefore (Equation 31)[8]

$$\begin{aligned} R(|00\rangle \longrightarrow |10\rangle) &= \frac{-\varepsilon_{\mathrm{a}}\varepsilon_{\mathrm{c}}V^{1c}}{\hbar(\varepsilon_{\mathrm{c}}^2 - \varepsilon_{\mathrm{a}}^2)} \\ &\quad \times \{\boldsymbol{\mu}_{\mathrm{A}}^{10}\boldsymbol{R}_{\mathrm{C}}\boldsymbol{\mu}_{\mathrm{C}}^{0c} + \boldsymbol{\mu}_{\mathrm{C}}^{c0}\boldsymbol{R}_{\mathrm{A}}\boldsymbol{\mu}_{\mathrm{A}}^{01}\} \\ &= \frac{-\varepsilon_{\mathrm{a}}\varepsilon_{\mathrm{c}}V^{1c}}{\hbar(\varepsilon_{\mathrm{c}}^2 - \varepsilon_{\mathrm{a}}^2)}\{\boldsymbol{\mu}_{\mathrm{C}}^{0c}\boldsymbol{\mu}_{\mathrm{A}}^{01}\boldsymbol{R}_{\mathrm{AC}}\} \end{aligned} \tag{66}$$

Figure 14 Diagram illustrating the geometry and coordinates for an A/C system. Note that τ is the angle taken in the anticlockwise direction between the *projections* of the EDTMs onto the y–z plane when the observer is looking down the x-axis. $0^{\circ} < \tau < 180^{\circ}$ if $\boldsymbol{\mu}^c \times \boldsymbol{\mu}^a\boldsymbol{R}_{\mathrm{AC}} > 0$ (i.e. if the three vectors form a right-handed parallelepiped), and $180^{\circ} < \tau < 360^{\circ}$ if $\boldsymbol{\mu}^c \times \boldsymbol{\mu}^a\boldsymbol{R}_{\mathrm{AC}} < 0$. CAR right-handed summarizes a mnemonic for the situation where $\boldsymbol{\mu}^c$, $\boldsymbol{\mu}^a$, and $\boldsymbol{R}_{\mathrm{AC}}$ form a right-handed axis system with $0^{\circ} < \tau < 180^{\circ}$.

Again using the coordinate system defined in Figure 14 we may write Equation (67)

$$R(\varepsilon_a) = \frac{-\varepsilon_a \varepsilon_c (\mu^a \mu^c)^2}{\hbar(\varepsilon_c^2 - \varepsilon_a^2) R_{AC}^2} \{\sin\alpha \sin\gamma \cos\tau + 2\cos\alpha \cos\gamma\} \times \sin\alpha \sin\gamma \sin\tau \quad (67)$$

which is usually easier to implement than Equation (66).

3 LINEAR DICHROISM

3.1 Introduction

LD is the difference in absorption of light linearly polarized parallel and perpendicular to an orientation axis, Equation (68):

$$\text{LD} = A_{\parallel} - A_{\perp} \quad (68)$$

LD is related to CD in that both require the difference between the absorbances of different polarized light beams to be measured and CD spectropolarimeters can be adapted to produce the required alternating beams of polarized light for LD. However, LD measurements are performed on systems that are either intrinsically oriented or are oriented during the experiment (Figure 16). The general LD references given below may be consulted for more details on the definitions and equations that follow. Rodger and Nordén[8] use the formalism adopted here.

The equations for LD were given in Equations (22) and (23) in the context of the interaction of radiation with matter. In order to understand LD more fully, consider what happens when a molecule absorbs a photon: absorption can be pictorially viewed as either the electric field or the magnetic field (or both) of the radiation pushing the electron density from a starting arrangement to a higher energy final one. The direction of net linear displacement of charge is known as the polarization of the transition. The polarization and intensity of a transition are characterized by the EDTM (see Equations 18 and 19) which may be regarded as the antenna by which the molecule absorbs light. Each transition thus has its own antenna and the maximum probability of absorbing light is obtained when the antenna and the electric field of the light are parallel.

Now imagine a linearly polarized light beam (Figure 16) and a sample of molecules all oriented in exactly the same way. If the normal absorption is first measured with the light polarized so that it is parallel to the direction of orientation of the sample and then measured when the light is polarized perpendicular to this direction, the difference between these two spectra is the LD spectrum. The two extreme situations are:

Figure 15 Exciton CD spectra for coupling 'short-axis' polarized transitions. (a) Illustrates characteristic form that results from cancellation of overlapping bands; - - - -, higher energy component; — – —, lower energy component; —, observed CD spectrum. (b) Illustrates the geometry of the system. (c) Shows the net spectra as a function of τ (assuming Gaussian band shapes for the two transitions).

Figure 16 Schematic illustration of LD.

1. If the polarization of the transition that is being probed is perfectly parallel to the orientation direction, then Equation (69) follows

$$\mathrm{LD} = A_{\parallel} - A_{\perp} = A_{\parallel} > 0 \tag{69}$$

2. If the polarization of the transition that is being probed is perpendicular to the orientation direction, then Equation (70) follows

$$\mathrm{LD} = A_{\parallel} - A_{\perp} = -A_{\perp} < 0 \tag{70}$$

For intermediate polarizations, the LD is between these cases. Thus, the polarization for a given transition can be determined from its LD spectrum if the orientation of the molecule is known; conversely, LD can be used as a probe of molecular orientation if the polarization of a transition moment within the molecule is known. In practice, one type of experiment is often performed, followed by the other, using different orientation methods.

The two extreme cases of Equations (69) and (70) are both illustrated in the simplified anthracene spectrum of Figure 17.[8] The spectrum is simplified in two ways:

1. perfect orientation of the molecules has been assumed, and
2. the long wavelength band has been assumed to be of pure short-axis polarization.

In reality perfect orientation is never achieved and there is a significant long-axis polarized component at ~320 nm due to coupling with the 250 nm band.

3.2 Orientation Parameters

A variety of different orientation methods for LD spectroscopy are outlined below. In practice, with the possible exception of a crystalline environment, the orientation is never perfect and we need to use the concept of an orientation distribution. In many cases, either the averaging inherent in the orientation method or the nature of the sample means that (at least) local uniaxial orientation can be assumed (Figure 18) and the simple orientation

Figure 17 (a) Stretched film orientation showing propagation direction, **k**, and electric field polarization, **E**, of the electromagnetic radiation, and (b) LD spectrum of long (z) and short (y) axis polarized transitions of an idealized (see text for assumptions) anthracene sample.

parameter S can be used. Equation (71) is then valid

$$\mathrm{LD}^{\mathrm{r}} = \frac{\mathrm{LD}}{A} = \frac{A_{\parallel} - A_{\perp}}{A} = \frac{3}{2}S(3\cos^2\alpha - 1) \tag{71}$$

LD^{r} is the so-called reduced LD, S may be viewed as a scaling factor defining the efficiency of macroscopic orientation, and α is an angle that specifies the orientation of the transition moment that is responsible for the absorption of light at the particular wavelength (if several transitions absorb at the same wavelength an average is obtained) with respect to the orientation axis (Figure 19). $S = 1$ for perfect orientation and $S = 0$ for random (i.e. no) orientation. In Equation (71) A is the absorption of the LD sample under isotropic (unoriented) conditions so $A_{\parallel}$, $A_{\perp}$, and A all have Cl as a common factor, hence when using LD^{r} it is not necessary to know the sample concentration or path length. If the sample is macroscopically as

Figure 18 Uniaxial and biaxial orientation. Uniaxial orientation requires all orientations on a cone about the orientation axis to be statistically equally probable. This may be due to static or dynamic factors.

Figure 19 Macroscopic and molecular axes systems and angles relating them.

well as molecularly uniaxial, such as molecules oriented in a polymer film drawn in one direction or polar molecules in an electric field, there is a simple relation between $A_{\parallel}$, $A_{\perp}$, and A which makes it unneccessary to measure all three quantities, Equation (72):

$$A = \tfrac{1}{3}(A_{\parallel} + 2A_{\perp}) \tag{72}$$

When the orientation method used in an LD experiment provides a uniaxial sample (Figure 18) and the sample molecules are also characterized by a unique axis around which all orientations are equally probable (so the molecule is 'rod-like'), we may then write, Equation (73):

$$S = \tfrac{1}{2}(3\langle\cos^2\theta\rangle - 1) \tag{73}$$

where θ is the angle between the macroscopic orientation direction Z and the molecular orientation axis z (Figure 19). θ is used instead of ζ, to which the same definition is given below, as a reminder that Equation (73) only holds for rod-like molecules in uniaxial samples. It is important to note that the averages of ($\cos^2$ angles) are appearing in the above equations. These are not the same as the ($\cos^2$) of (average angles), though in practice we usually have to ignore what can be a considerable difference.

More generally, instead of a single orientation parameter we need to have three since in some LD experiments, including rectangular squeezing of a gel or when the light is incident radially upon a cylindrical couette flow cell (Figure 20), the system behaves as if the orientation were biaxial (Figure 18) for which the constant probability contour for a given molecular axis traces out an ellipse. (Note: flow-oriented DNA, see below, is uniaxially oriented due to the helical nature of the molecule.) A laboratory (macroscopic) axis system $\{X, Y, Z\}$ is defined first, such that X is the direction of propagation of the incident radiation and Z is the macroscopic direction of orientation. Y then completes the right-handed axis system. The more general definition of LD is then, Equation (74)

$$\mathrm{LD} = A_Z - A_Y \tag{74}$$

(cf. Equation 23). Similarly, we write Equation (75)

$$\mathrm{LD}^{\mathrm{r}} = 3\left(\frac{A_Z - A_Y}{A_X + A_Y + A_Z} \right. = 3(\langle\hat{\mu}_Z^2\rangle - \langle\hat{\mu}_Y^2\rangle) \tag{75}$$

When studying LD it is also convenient to define the molecular axis system, $\{x, y, z\}$. We take z to be the molecular orientation axis, i.e. the axis in the molecule which has maximum value shown by Equation (76) of

$$\langle\cos^2\zeta\rangle \tag{76}$$

where ζ is the angle between z and Z. x is the axis perpendicular to z that has the smallest value shown by Equation (77) of

$$\langle\cos^2\xi\rangle \tag{77}$$

where ξ is the angle between x and Z. ψ is similarly the angle between y and Z. z is often, but not always, the highest order symmetry determined axis.

The general definitions of the orientation parameters are given by Equation (78)

$$\boldsymbol{S} = \begin{matrix} S_{xx} & S_{xy} & S_{xz} \\ S_{yx} & S_{yy} & S_{yz} \\ S_{zx} & S_{zy} & S_{zz} \end{matrix}$$

$$= \begin{matrix} \tfrac{1}{2}(3\langle\cos^2\xi\rangle - 1) & 0 & 0 \\ 0 & \tfrac{1}{2}(3\langle\cos^2\psi\rangle - 1) & 0 \\ 0 & 0 & \tfrac{1}{2}(3\langle\cos^2\zeta\rangle - 1) \end{matrix} \tag{78}$$

Figure 20 Flow orientation in a coaxial (couette) flow cell with radial incident light. The total light path is typically 1 mm. PMT = Photomultiplier tube.

Since we defined z to be the most oriented molecular axis, and x to be the least oriented Equation (79) follows:

$$S_{zz} \geq S_{yy} \geq S_{xx} \tag{79}$$

Further, the trace of the orientation tensor is zero so that, Equation (80):

$$S_{xx} + S_{yy} + S_{zz} = 0 \tag{80}$$

For rod-like molecules $S_{xx} = S_{yy}$ and S for the uniaxial case is S_{zz}.

In solving any particular problem, the positions of $\{x, y, z\}$ are seldom known, so it is usually convenient first to choose a temporary molecular axis system $\{x', y', z'\}$ which probably bears no relationship to the orientation axis system but is convenient for our analysis (see example below). Analogously to the definitions we used with the 'true' molecular axis system, the orientation of the macroscopic orientation axis Z in the new coordinate system may then be written, Equation (81), as the vector

$$(\cos\xi', \cos\psi', \cos\zeta')_{x',y',z'} \tag{81}$$

also, Equation (82)

$$\boldsymbol{S}' = \begin{matrix} S_{x'x'} & S_{x'y'} & S_{x'z'} \\ S_{y'x'} & S_{y'y'} & S_{y'z'} \\ S_{z'x'} & S_{z'y'} & S_{z'z'} \end{matrix} = \begin{matrix} \frac{1}{2}(3\langle\cos^2\xi'\rangle - 1) & 3\langle\cos\xi'\cos\psi'\rangle & 3\langle\cos\xi'\cos\zeta'\rangle \\ 3\langle\cos\xi'\cos\psi'\rangle & \frac{1}{2}(3\langle\cos^2\psi'\rangle - 1) & 3\langle\cos\psi'\cos\zeta'\rangle \\ 3\langle\cos\xi'\cos\zeta'\rangle & 3\langle\cos\psi'\cos\zeta'\rangle & \frac{1}{2}(3\langle\cos^2\zeta'\rangle - 1) \end{matrix} \tag{82}$$

For planar molecules in uniaxially oriented systems, $x' = x$ so $\xi' = \xi$. It follows that,[8,34]

$$\mathrm{LD}^{\mathrm{r}} = 3(S_{y'y'}\sin^2\alpha' + S_{z'z'}\cos^2\alpha' + S_{y'z'}\sin\alpha'\cos\alpha') \tag{83}$$

where α' is the angle between the transition dipole moment and axis z'. The three orientation parameters in Equation (83) are three unknowns, so three different transitions of known polarization are needed to determine them. The position of z is almost determined from

Equation (84)[8,34]

$$\tan(2\beta) = \frac{S_{y'z'}}{S_{z'z'} - S_{y'y'}} \quad (84)$$

where β is the angle between z' and z. Either chemical intuition or another experiment such as fluorescence polarization anisotropy[35] is required to determine on which side of z', z lies. It is often apparent upon inspection.

3.3 Molecular Alignment Techniques

In addition to the requirement of linearly polarized light for LD, LD experiments are made technically demanding because of the need to orient the sample. The orientation method used for this depends on the sample. Long polymers may be oriented by shear flow whereas small molecules require a stronger orienting force. A selection of orientation methods is described below. More details may be found in the general LD references.

3.3.1 Stretched Polymers

Small molecules can often be absorbed into polymer films, usually polyethylene or poly(vinyl alcohol) (both can be used well into the UV even down to 200 nm) depending on the polarity of the analyte. When the film is mechanically stretched, either before or after the small molecules are added, the absorbed molecules align their long axes preferentially along the stretch direction (Figure 17). There has been no evidence that a solute is better oriented when introduced into the film before stretching compared with it being added after stretching; with poly(vinyl alcohol); however, the film is usually cast containing the analyte so it cannot be added after stretching.

3.3.2 Flow Orientation

Long polymers may be oriented by the viscous drag caused when a solution is flowed between narrow walls.[36] Depending on the cell design, the light is then propagated either along the flow direction or perpendicular to it. This technique is commonly used for LD studies of DNA (the DNA needs to be at least of the order of 1000 base pairs in length to get significant orientation). The most successful flow cell has proved to be a cylindrical couette flow cell where the solution containing the DNA is subjected to a constant gradient over the annular gap between two coaxial cylinders one of which is rotating (Figure 20).

3.3.3 Electric Field Orientation

Effective uniaxial orientation for polar or polarizable molecules (including DNA since its ionic environment is polarizable) may be achieved by an electric field between two parallel plates.[37] Electric orientation is conceptually simpler than flow orientation, and the data can be fairly easily extrapolated to infinite orientation which contrasts with the situation for flow orientation. Heating effects may be circumvented by using pulsed field techniques, which additionally enable the study of relaxation phenomena. However, the pulsed nature of the field generally requires each electric dichroism experiment to be performed at a fixed wavelength or else a diode array system to be used; it is also usual to measure $A_{\parallel}$ and A (the unoriented absorbance) rather than $A_{\perp}$ (as the orientation is uniaxial, only two of the three absorbances need be determined independently as discussed above).

3.3.4 Squeezed Gel Orientation

The method of orientation that has proved most successful for membrane proteins, particularly photosynthetic ones, is to embed the protein in a gel (usually polyacrylamide) and then physically squeeze the gel either unidirectionally or bidirectionally (Figure 21).[28] The main shortcomings of the gel orientation technique are its limitation to wavelengths longer than 250 nm, and the limited dynamic range of deformation.

3.3.5 Migrative Orientation

While migrating in an electrophoresis gel, DNA is macroscopically oriented and gives an LD signal.

3.3.6 Magnetic Field Orientation

Magnetic fields may be used to orient molecules in much the same way as electric fields, however, the effect is small and this method is not widely used unless the particles are large (such as chloroplasts) and carry substantial magnetic dipole moments.

Figure 21 Principles of biaxial and uniaxial squeezing of gels.

3.3.7 Crystalline Samples

If the absorbance is not too large for the spectrometer to measure, crystals may be used for LD studies.

3.3.8 Liquid Crystal Orientation

The molecules within a liquid crystal are oriented with respect to one another and by sandwiching the liquid crystal between two quartz plates, macroscopic orientation may be achieved.[38] The sample must be tilted with respect to the light beam to get an LD signal. Molecules dissolved in a liquid crystal may also have a preferential orientation.

3.3.9 Orientation by Evaporation, for Example onto Quartz

This method may be appropriate for some samples, particularly planar aromatic molecules that readily adsorb onto quartz. The quartz plate has to be tilted for LD measurement.

3.4 Examples of Linear Dichroism Data

3.4.1 DNA

The absorption, and hence LD, spectra of nucleic acids in the easily accessible UV region of the spectrum (down to 180–190 nm) are dominated by the $\pi \rightarrow \pi^*$ transitions of the purine and pyrimidine bases which, by symmetry, are all polarized in the plane of the bases. If DNA is in the idealized B-DNA form with the DNA bases perpendicular to the helix axis[39] then a flow oriented DNA sample (Figure 20) should have its LD^r across the whole spectrum constant and negative. In practice, there is some variation in magnitude (Figure 22) which indicates that the bases are tilted.

Normal B-DNA, which according to the classical fiber structure has $\theta_X = -2.1^\circ$ and $\theta_Y = 4.0^\circ$ (Figure 23, though fiber B-DNA has 10 base pairs per turn of the helix rather than the 10.4–10.6 of solution DNA), should display only small variations in LD^r in the wavelength region 230–300 nm with $LD^r/S = -1.47 \pm 0.02$. A-form DNA, with $\theta_X = 19.3^\circ$ and $\theta_Y = -3.2^\circ$, is, however, expected to exhibit a sloping LD^r, with LD^r/S varying from about -1.2 at 230 nm to about -1.4 at 300 nm, depending on the sequence of the DNA.[40] Z-DNA is longer and stiffer and so is expected to have a significantly larger LD signal than the same sequence of B-DNA as shown in Figure 22.

LD data has been analyzed to determine the average values for base roll, tilt, twist, and slide for the different DNA bases in solution B-DNA; a value of $\alpha = 73^\circ$ is appropriate for purines, whereas $\alpha = 65^\circ$ for pyrimidines.[40] These results are dependent on the accuracy of the assignment of base transition

Figure 22 Absorbance (a), LD (b), and LD^r (c) spectra of B-form and Z-form poly[d(G–C)]$_2$ (60 μM in 10 mM NaCl, 1 mM cacodylate buffer, pH = 7). The Z-form is induced by adding 40 μM $[Co(NH_3)]^{3+}$. The DNA has been flow oriented. As all $\pi \rightarrow \pi^*$ transitions of the bases are polarized approximately perpendicular to the helix axis, the LD signals are negative. —, B-DNA; - – -, Z-DNA.

polarizations, intensities, and bandwidths. An effective average value of 84° for α at 260 nm is often assumed for B-DNA based on the fiber diffraction structure and an estimate of contributions from different transitions to the total LD.[42]

3.4.2 Linear Dichroism of DNA-bound Ligands

Once the orientation of DNA itself is understood a next step is to use LD to probe the binding and orientation

Figure 23 Geometry parameters for DNA as used in the text.

on DNA of small ligand molecules and even proteins. A key feature of such LD studies is that if there is no specific binding, then there will be no LD of the ligand transitions. Conversely, the presence of an LD signal from an absorption band of the putative ligand immediately implies that it is bound. Although LD cannot tell us where a ligand binds to DNA, it can be used to determine the orientation of the ligand on the DNA (if the ligand's transition moments have been assigned). This often provides significant clues as to the binding mode. A ligand may bind to DNA in a number of different types of site, as well as with sequence and orientation preferences. Broadly speaking a ligand may bind in the following ways.

1. *Externally* bound to the phosphate backbone: this is usually orientationally fairly nonspecific and the induced LD (and CD) is correspondingly small.
2. *Intercalated* between DNA bases: this mode requires planar aromatic molecules and the DNA to unwind and open up a slot between adjacent base-pairs so the ligand may be sandwiched between them. The DNA is stiffer and locally better oriented near the intercalation site, so the LD^r of an intercalator is usually slightly larger (more negative) at 260 nm than that of the average DNA base. If the bases are tilted, then the intercalator follows that tilt and this may be apparent in the LD^r. For example, the short axis of 9-hydroxyellipticine aligns with the long axis of the base-pair pocket and has a slightly smaller LD^r signal than the long axis of the molecule which is perpendicular to the pocket and also more perpendicular to the helix axis than the base pairs (Figure 25).
3. In the *minor groove*: this mode is frequently adopted by aromatic molecules containing internuclear bonds with some rotational freedom. For example, long molecules such as netropsin, distamycin, Hoechst 33258, and 4′,6-diamidino-2-phenylindole (Figure 24), which can fit snugly into the minor groove with the molecule following the curvature of the groove but are too large to fit into an intercalation site, favor this mode of binding. The long axis of

Figure 24 The intercalators (a) ethidium bromide and (b) 9-hydroxyellipticine, and some minor groove binders: (c) netropsin, (d) Hoechst 33258, and (e) 4′,6-diamidino-2-phenylindole.

Figure 25 Some examples of LD spectra for DNA bound ligands. (a) 9-Hydroxyellipticine (1–10 μM in 2.5 μM increments, signal increases with ligand concentration) with 100 μM calf thymus DNA in NaCl (20 mm) and phosphate buffer (1 mM, pH 7);[41,45,46] (b) *trans*-bis-(4-*N*-methylpyridiniumyl)diphenylporphyrin (5 μM) with 40 μM calf thymus DNA in phosphate buffer (1 mM, pH 7) and varying NaCl concentrations (see figure insert) showing the change in binding orientation as a function of ionic strength. Signal increases with ligand concentration.

such molecules is oriented at about 45° to the helix axis and the short axis polarized transition perpendicular to it (approximately parallel to the base transitions). This mode is selective (or even specific) for adenine–thymine-rich DNAs as the guanine amino group sterically hinders the minor groove of guanine-containing sequences.

4. In the *major groove*: this type of binding is found for several regulatory proteins and there is enough space to accommodate most smaller ligands in a variety of orientations.

Some examples of LD spectra for DNA bound ligands are given in Figure 25.

3.4.3 Determination of the Molecular Orientation Axis of a Molecule in a Stretched Film

Infrared LD is particularly useful for determining orientations, particularly of small molecules in stretched films, because the polarization of vibrations are often known simply from their position in the spectrum. For example, riboflavin has three infrared bond stretching vibrations.[35] For convenience we choose the primed axis system as illustrated in Figure 26. The values of the LD^r for each transition are also given in Figure 26.

For the three transitions for which the data is given in Figure 26, Equation (83) leads to Equation (85)

$$\begin{aligned} +0.070 &= 3(S_{z'z'}) \\ +0.580 &= 3(0.030S_{z'z'} + 0.970S_{y'y'} - 0.174S_{y'z'}) \\ +0.110 &= 3(0.250S_{z'z'} + 0.750S_{y'y'} - 0.433S_{y'z'}) \end{aligned} \quad (85)$$

From which Equation (86) follows

$$S_{z'z'} = 0.024 \quad S_{y'y'} = 0.256 \quad S_{y'z'} = 0.373 \quad (86)$$

Thus, β (Equation 84) either equals 61° or 151°. By inspection of Figure 26, we conclude that $\beta = 61°$ is correct and the dashed line of Figure 26 is the molecular orientation axis z.

4 INSTRUMENTATION AND THE DICHROISM EXPERIMENT

4.1 Circular Dichrographs (Spectropolarimeters)

The essential features of a CD spectropolarimeter are a source of (more-or-less) monochromatic left and right circularly polarized light and a means of detecting the difference in absorbance of the two polarizations of light. The normal method of achieving these requirements, because the CD of molecules is generally quite weak compared with the total absorbance signal, is to implement a polarization phase-modulation technique. A photoelastic modulator (PEM) (in older instruments a Pockels cell) produces alternatively right and left circularly polarized

Figure 26 Riboflavin indicating the temporary axis system used in the calculation and the polarizations and LD^r values for the three transitions used in the text. Data are from Matsuoka and Nordén.[34]

light. The light intensity is constant, but upon passage through a sample exhibiting CD an intensity fluctuation (corresponding to the different absorptions of left and right circularly polarized light) that is in phase with the modulator frequency appears. The unabsorbed photons hit a photomultiplier tube which produces a current whose magnitude depends on the number of incident photons.

The light source in most CD instruments is a xenon arc lamp for UV and visible CD measurements. This means that the instrument has most sensitivity in the 300–400 nm region of the spectrum. The fact that a lamp is getting old becomes apparent by decreased light intensity in the 200 nm and 700 nm regions of the spectrum. The optics of a typical CD machine are illustrated in Figure 27. A series of mirrors and prisms and slits are used to produce collimated monochromatic radiation (in reality it is not monochromatic but has a well-defined wavelength range, typically of 0.5–2 nm). This light is then linearly polarized and subsequently circularly polarized. The conversion of linearly polarized light into circularly polarized light is achieved by the PEM.

The PEM consists of a piece of crystal quartz mechanically coupled (glued) to a piece of isotropic (silica) quartz, the light passing through the latter. The quartz plate is oriented so that light polarized (say) vertically travels through it at one speed and light polarized horizontally travels more slowly. If the linearly polarized light is incident on the plate at a 45° angle, then it may be considered as split into equal magnitude vertical and horizontal components. The PEM exhibits birefringence so that $(n_Z - n_Y) \neq 0$, i.e. the refractive indices n_Z and n_Y for vertical and horizontal polarizations are different. During passage through the PEM the phase difference between the vertical and horizontal light beam components will amount to, Equation (87):

$$\delta = \frac{2\pi D}{\lambda} = \frac{2\pi d(n_Z - n_Y)}{\lambda} \tag{87}$$

where d is the thickness of the PEM, λ is the wavelength of the light, and D is the path difference between the light components. At a certain value of $(n_Z - n_Y)$, δ will be equal to $\pi/2$ and D equal to $\lambda/4$, making the so-called 'quarter wave' plate required to produce circularly polarized light.

An ac (alternating current) voltage is applied to the crystal part, causing the whole PEM assembly to oscillate (typically at 50 kHz). By adjusting the voltage amplitude so that the birefringence amplitude corresponds to the quarter wave condition at each λ, the time dependence of $(n_Z - n_Y)$ as it oscillates between $+|n_Z - n_Y|$ and $-|n_Z - n_Y|$ gives light that is alternately left and right circularly polarized. The polarized light thus produced then passes through the sample compartment (and the sample) and what is not absorbed is detected by the photomultiplier tube. If the sample has no CD the photomultiplier current will be a constant, direct current (dc) with a magnitude determined by the normal absorbance of the sample. If the sample exhibits CD

Figure 27 Schematic diagram of the optics of a CD spectropolarimeter. M denotes mirror, P denotes prism, and PO denotes polarizer. As illustrated the monochromator prisms (P1 and P2) are also the polarizers; to improve the polarization further a series of tilted quartz plates are inserted in the light path preceding the PEM. Sample and photomultiplier tube are attached after the PEM.

the photomultiplier current will also show an oscillating component (ac). The CD is obtained as the ratio between the ac and dc components. Its sign is determined from the phase of the ac component using a lock-in amplifier that has the ac voltage of the PEM as a time reference.

With both DNA and protein CD experiments it is important to think carefully about the buffer to be used. CD instruments are single beam spectrometers and so there is no automatic compensation mechanism for buffer absorbance as there is for normal absorbance spectroscopy where the buffer can be placed in a reference cuvette. Many CD experiments fail or give nonsense results as all the light is absorbed by the nonchiral parts of the solution.

4.2 Design and Implementation of an Linear Dichroism Experiment

The components of an LD experiment are a source of linearly polarized light, a means of detecting how much light is absorbed, a method of orienting the sample (as discussed above), and a way to change the relative orientations of sample and light beam. There are two main methods for measuring LD spectra. The one requiring less specialized equipment is the two-spectra method. Using a double beam spectrophotometer equipped with a polarizer (e.g. of Glan type) which is not sensitive to beam divergence, the sample is oriented parallel to the polarization direction of the polarizer to obtain $A_{\parallel}$. It is then oriented perpendicular to the polarization direction of the polarizer to obtain $A_{\perp}$. (Alternatively, the polarizer may be rotated, in which case any effect of internal polarization of the light by the optics of the spectrometer must be considered.)

The other method, the differential method, is much easier to implement and a wider range of sample orientation techniques may be used. However, much more sophisticated instrumentation is required as the phase-modulation technique of a circular dichrometer is used, either by supplementing the latter with a quarter wave device (e.g. a Fresnel rhomb or an Oxley prism to achieve achromacy[3–7]) or by increasing the driving voltage of the PEM and doubling the beat frequency of the lock-in amplifier. A factor of two increase in the voltage across the quarter wave PEM that turns linearly polarized light into alternating left and right circularly polarized light for CD measurements, turns the PEM into a half-wave plate that produces alternating pulses of orthogonal beams of linearly polarized light for LD spectroscopy. The differential method has the advantage of being extremely sensitive, needing only very low sample orientation or concentration.

Absorption and luminescence detectors convert radiant energy directly into an electrical signal or into another physical quantity, such as heat or resistance, which is subsequently converted into an electrical signal. Detectors are subdivided into three main categories depending upon their mode of operation. Thermal detectors sense the change in temperature that results from the absorption of incoming radiation. Photon detectors, on the other hand, respond to incident arrival rates rather than to photon energies. Multichannel detectors are arrays of multiple thermal detectors or arrays of multiple semiconductor detectors. Detectors of the third category permit simultaneous detection of dispersed radiation over a broad spectral wavelength region. Absorption and luminescent detectors are components in UV (ultraviolet)-visible, infrared (IR) and atomic absorption spectrophotometers and in fluorescence, phosphorescence, Raman and atomic emission spectrometers.

1 GENERAL DETECTOR REQUIREMENTS AND PERFORMANCE CHARACTERISTICS

Commercial absorption and luminescence detectors can vary widely in terms of their sensitivity, spectral response, response time, linearity and signal-to-noise ratios (S/Ns). Specific analytical applications often dictate the minimum performance characteristics that the radiation detector can possess. For example, in the case of a photomultiplier tube (PMT) the minimum requirements for measuring fluorescence lifetimes by both pulse and phase-modulated methods include: (1) fast time-response of typically 1.5 ns risetime, (2) electron gains exceeding 5 million, (3) low noise of less than 100 counts s^{-1}, (4) low transit-time dispersion with point of illumination on the cathode (i.e. <20 ps mm^{-1}), and (5) low afterpulsing from ion or photon feedback to the photocathode and low repulsing from photoelectron generation at the dynodes. The characteristics given below are commonly employed in evaluating the different absorption and luminescence detectors for a particular analytical application.

Response time is the measure of the detector's ability to detect rapid changes in the incident radiant power. Quantitatively, the response time is evaluated in terms of the time constant $\tau = 1/(2\pi f_c)$, where f_c is the frequency at which the incident radiant power has fallen to 0.707 of its maximum value when a sinusoidal input of frequency f_c is incident on the detector. The risetime is defined as the time required for the output to increase for 10–90% of its final value as a result of an instantaneous increase in the radiant power reaching the detector.

Linearity is a statement of whether the electrical signal produced by the detector, $S(\lambda)$, is directly proportional to the incident radiant power, $R(\lambda)$, Equation (1)

$$S(\lambda) = Q(\lambda)\, R(\lambda) \tag{1}$$

The sensitivity, $Q(\lambda)$, is defined as the slope of a plot of the electrical output of the detector versus incident radiant power, $R(\lambda)$. For photon detectors, and for many thermal detectors, both $Q(\lambda)$ and $R(\lambda)$ are wavelength dependent. The sensitivity of a given detector is thus specified at a particular wavelength. Usually, radiation detectors exhibit linearity over a limited range of incident radiant power. The total range, expressed in powers of 10, for which the electrical signal is linear is called the linear dynamic range. The dynamic range is defined as the total range of incident radiant power over which the detector is responsive.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

Many real detectors exhibit a small, constant response even in the absence of radiation. The small electrical output is known as the dark current. Photoemissive detectors (a type of photon detector) exhibit dark currents due to thermal emission of electrons from a photosensitive material. Dark currents in photoconductive detectors (a second kind of photon detector) occur from the elevation of electrons from the valence band to the conduction band through thermal processes. In such cases, the electrical signal contains a contribution from the dark current, S_{dark}, Equation (2)

$$S(\lambda) = Q(\lambda)\, R(\lambda) + S_{\text{dark}} \tag{2}$$

Dark currents can in principle be subtracted from the total electrical signal, $S(\lambda)$. Dark current measurements are made with the entrance optics of the spectrometer closed. Over short measurement periods, S_{dark} is usually constant. Many of the commercial spectrophotometers that are equipped with detectors that produce dark currents also contain compensating circuits to minimize the magnitude of S_{dark} when measurements are made.

Gain is an important consideration when comparing the performance of different PMTs. Briefly, electrons are emitted from the photocathode surface of the PMT when it is exposed to radiation. The photoejected electrons are captured by an electrical potential and accelerated toward an electrode (dynode) coated with a compound (e.g. CuBe, BeO, GaP or CsSb) that ejects several electrons when struck by a high-energy electron. These new electrons are in turn accelerated toward another dynode (operated at a potential more positive than the preceding dynode), where the process is repeated and further multiplication occurs. Ideally, the electron gain of the PMT, G, is expressed as $G = (\Gamma)^n$, where Γ is the average number of electrons ejected at each dynode per impinging electron, and n refers to the number of dynodes inside the PMT. The exact numerical value of Γ depends upon the imposed potential difference between two successive dynodes and upon the chemical nature of the material that coats the dynode. For most commercial PMTs, Γ ranges between $\Gamma = 3$ and $\Gamma = 10$; however, several of the newer GaP coatings can achieve values as large as $\Gamma = 50$. Typical gains associated with PMTs used in commercial spectrophotometers vary from a lower limit of approximately $\Gamma \approx 10^3$ to an upper limit of about $\Gamma \approx 10^8$.

Electrical signals from the detector in a spectrometer almost always vary with time, even when the power of the incoming incident radiation is constant. Noise is defined as the unwanted fluctuation in the desired signal which obscures its accurate quantification. Noise is associated with each individual component of a spectrometer. The noise that is finally observed is a complex composite of the contributions from the different recognizable kinds of instrument noise that include thermal (or Jonson) noise, shot noise (also called Shottky or quantum noise) and flicker noise.

Thermal noise is caused by the thermal agitation of electrons or other charge carriers in resistors, capacitors, radiation detectors and other resistive elements in the spectrometer. Charge inhomogeneities are periodically created as a result of the random thermal agitation of charged particles. The charge inhomogeneities lead to voltage fluctuations which appear in the readout as unwanted noise. The magnitude of thermal noise is given by[1]

$$v_{\text{rms}} = (4\,kTR\Delta f)^{0.5} \tag{3}$$

where v_{rms} is the root-mean-square noise voltage in frequency bandwidth Δf. In Equation (3) k is the Boltzmann constant, T denotes the absolute Kelvin temperature, and R is the resistance in ohms of the resistive element. Examination of Equation (3) reveals that thermal noise can be reduced significantly by lowering the temperature of the component(s) and by lowering the circuit resistance. In practice, detector noise is often reduced by cooling. For example, lowering the temperature of a UV-visible photodiode array (PDA) from ambient room temperature to 77 K with liquid nitrogen would lead to a 50% reduction in the thermal noise.

Shot noise is encountered whenever electrons or other charged particles cross a junction. In radiation detectors such junctions are found at the pn interfaces of semiconductors, and in the evacuated space between the anode and cathode of vacuum tubes and photocells. The currents are composed of a series of quantized events, that is, the transfer of individual electrons across the junction. Under these conditions, the Poisson probability distribution applies and the statistical fluctuations in the average direct current, I, are given by[1]

$$i_{\text{rms}} = (2Ie\Delta f)^{0.5} \tag{4}$$

where i_{rms} is the root-mean-square current fluctuation. In Equation (4) e is the charge on the electron and Δf is the bandwidth of the frequency being considered. The sources of noise, as well as their mathematical treatment, are discussed in greater detail elsewhere.[1]

The S/N is mathematically defined as

$$\text{S/N} = \frac{\text{Signal}}{N_{\text{rms}}} \tag{5}$$

the ratio of the analytical signal, S, and the root-mean-square noise in the analytical signal, N_{rms}. In many spectrophotometric measurements, the overall noise level remains fairly constant and is independent of the measured electrical signal. Noise contributions thus become increasingly more important as the detector

signal decreases. The S/N provides a more meaningful measure of instrument performance than does the noise level alone. A S/N of 1000 corresponds to a relatively high precision measurement.

Multichannel charge-coupled devices (CCDs) and PDA detectors can improve the S/N for spectrophotometric measurements in two ways. First, an array detector benefits from the Fellgett advantage. The array detector monitors several wavelength regions simultaneously. The entire analysis time is spent accumulating experimental absorption/luminescence data at all wavelengths. Conventional scanning spectrophotometers, on the other hand, spend only a small fraction of the total analysis time at any one wavelength. The total analysis time is generally divided into equal time intervals. Only one time interval is spent at any given wavelength. Simultaneous wavelength detection increases the S/N by a factor of $N^{0.5}$, where N is the number of spectral regions viewed (or alternatively the number of time intervals used) during the analysis time, which is held fixed. Secondly, CCD array detectors lead to an increased S/N because the individual pixels frequently outperform PMTs. This is not the case, however, with the photodiodes. The high quantum efficiency and low read noise of today's modern solid state CCD detectors, combined with the quiet-amplification of solid state electronics, yield S/Ns similar to (or better than) those obtainable using PMTs. Moreover, both photodiode and CCD spectrophotometers have fewer movable parts, which greatly improves both wavelength accuracy and precision.[2]

Two additional quantities have been defined to describe the noise characteristics of absorption and luminescence detectors. The noise equivalent power, Φ_{noise}, is the root-mean-square power in watts that would be needed by a sinusoidally modulated input incident on the radiation detector to cause an electrical signal equal to the root-mean-square dark noise, σ_{dark}, in a 1-Hz bandwidth, i.e. $\sigma_{dark} = \Phi_{noise}(\lambda)R(\lambda)$. As indicated by the mathematical relationship, Φ_{noise} is wavelength dependent. A meaningful statement of the noise equivalent power requires that the wavelength of measurement be specified. The modulation frequency, detector area and electrical bandwidth should also be stated. Associated with noise equivalent power is the detectivity, D, which is defined as the reciprocal of Φ_{noise}. The detectivity (expressed in 1/watts) is a measure of minimum detectability.[1]

2 PHOTOCATHODE AND PHOTOSENSITIVE MATERIALS

All photon detectors use a photosensitive material to absorb the incoming incident radiation. For photoemissive photon detectors the absorbed energy leads to the emission of electrons and the subsequent development of a photocurrent that is proportional to the amount of absorbed radiation (see Equation 1). In the case of photoconductive photon detectors the absorbed radiation promotes electrons into conduction bands, with detection now based upon the resulting enhanced conductivity.

The photocathode is an important component of a photoemissive detector. Currently, two types of photocathode are used in commercial detectors. The opaque photocathode consists of a thick photoemissive material which emits electrons from the side struck by the incoming incident radiation. The transparent photocathode has the photoemissive material deposited on planar or spherical-section windows such that electrons are emitted from the backside of the photocathode opposite the incoming radiation. The spectral response of the photocathode is governed by the photoemissive material, and also by the window material in the case of the transparent photocathode. The short-wavelength limit of the transparent photocathode is determined to a large extent by the window material. Window inserts of fused silica or quartz extend the range into the far UV.

The photoemissive process responsible for converting the radiant energy into an electrical signal involves three steps. First, the photon is absorbed by the photosensitive material of the photocathode and energy is transferred from the photon to the electron. The transferred energy causes the electron to move toward the material–vacuum interface. If the electron has sufficient energy it escapes over the potential barrier at the surface into the vacuum of the tube. The energy required to release the electron from the surface corresponds to the photocathode work function, $E_{cathode}$. The energy can be used to calculate the threshold wavelength, λ_{thresh}, through the relationship λ_{thresh} (in nm) $= hc/E_{cathode} = 1240/E_{cathode}$, where h is Planck's constant and c is the speed of light. The work function represents the energy that must be given to a Fermi level electron of the metal to raise it up to the potential energy of the metal–vacuum interface. Typical work functions for pure materials range from 2–5 eV. Semiconductor materials can have substantially lower work functions.

Figure 1 depicts the radiant sensitivity (in milliamps per watt) of several types of photoemitter as a function of wavelength. Careful examination of the various curves reveals that the most sensitive photocathode compositions are the bialkali types (117 and 115), which have nominal compositions of K/Cs/Sb. Red-sensitive materials are the multialkali types (e.g. S-20 and 112 with $Cs/Na_2/K/Sb$) or Ag/O/Cs formulations (denoted as S-1). The latter photoemitter is useable up to a wavelength of about $\lambda \approx 1000$ nm. The UV end of the spectrum can be reached by coupling virtually any type of photoemitter with an optically transparent fused silica

Figure 1 Spectral response curves of select photoemissive materials. Nominal compositions of the various materials are: S-1 (Ag/O/Cs), S-11 (Cs_3/Sb), S-4 (Cs_3/Sb), 117 (K/Cs/Sb); 115 (K/Cs/Sb); and 128 (Ga/As). (Redrawn with permission from F.E. Lytle, *Anal. Chem.*, **46**, 545A–557A (1974). Copyright American Chemical Society.[3])

Figure 2 Approximate spectral ranges of various semiconductors used in photoconductive detectors. The actual spectral range is dependent upon temperature, detector design and semiconductor position. (Redrawn from J.M. Harnly, R.F. Fields, *Appl. Spectrosc.*, **51**, 334A–351A (1997). Copyright Society for Applied Spectroscopy.[2])

window. The Ga/As photoemitters exhibit a fairly flat spectral response from $\lambda \approx 440$ nm to $\lambda \approx 880$ nm, and can be used in spectrometers to measure radiant energy in the 200–940 nm spectral region.

Photoconductive detectors operate differently than the photoemissive detectors that were just discussed. A pn-semiconductor junction (a diode) is reversed-biased leading to the formation of a depletion layer. No current flows in the absence of electromagnetic radiation. When photons interact with the detector, electrons are promoted from the valence band to the conduction band where they act as charge carriers. In the photovoltaic mode of operation, an external circuit monitors the small potential change that develops across the semiconductor as electrons are promoted into the conduction band. The current generated by the electron–hole pairs is measured in the photoconductive mode of operation. The measured signal in both cases is proportional to the instantaneous photon flux at the pn-semiconductor junction. Figure 2 depicts the approximate spectral range of the various semiconductors used in commercial absorption and luminescence detectors. At present silicon semiconductors are used for applications in the UV and visible spectral regions. Recent technological advances in fabricating materials based upon the group 13 and group 15 nitrides may in future years lead to new semiconductor materials for the UV spectral region.[4–6]

Although most semiconductor diodes operate as photoconductive detectors, a Schottky diode functions in a similar fashion to a photoemissive detector. Schottky diodes are fabricated on silicon substrates with deposition of either iridium or platinum. The absorbed radiation causes electrons to be emitted from a metal layer having a low work function, rather than creating electron–hole pairs that would be expected in a semiconductor-type material. The emitted electrons are collected in the potential wells of neighboring associated structures.

3 PHOTOVOLTAIC OR BARRIER-LAYER CELLS

The photovoltaic cell (also called a barrier-layer cell) is a very simple absorption and luminescence detector for measuring radiation in the visible spectral region. The device consists of a flat iron or copper electrode upon which has been deposited a very thin layer of semiconducting material (e.g. selenium). A very thin transparent metallic film of silver or gold is sputtered over the semiconducting material. The metallic film acts as the collector electrode and the entire assembly is protected by a transparent lacquer coating. A typical photovoltaic cell is depicted in Figure 3.

A photovoltaic cell operates as follows. Electrons at the selenium–silver surface are excited whenever radiation of sufficient energy falls upon the semiconductor surface. Electron excitation leads to the formation of conduction electron–hole pairs. The electrons then migrate toward the deposited metallic silver (or gold) film, while the holes travel toward the iron (or copper) electrode. The liberated electrons subsequently pass through the external circuit

Figure 3 Schematic design of a typical photovoltaic (barrier-layer) cell.

to interact with the holes. An electrical current develops from the electron–hole movement. Photovoltaic cells typically generate currents on the order of 10–100 mA, which are large enough to be measured with a microammeter. The measured photocurrent is directly proportional to the number of photons that strike the semiconductor surface, provided that the resistance of the external microammeter circuit is sufficiently small ($<400\,\Omega$).

A photovoltaic cell (with selenium semiconductor) is primarily used in filter photometers to monitor radiation in the visible spectral region. The greatest sensitivity of the cell is for the green through yellow wavelengths. The current output of the cell is not easily amplified and this restricts the use of the cell to those applications where fairly high levels of illumination exist. High illumination levels eliminate the need to amplify the electrical signal.

The photovoltaic cell does provide an economical, low-cost means for measuring radiant power in the visible spectral region, particularly at high levels of illumination. The cell does suffer from lack of sensitivity at low levels of illumination and amplification of the electrical signal is not easily accomplished. Photovoltaic cells also experience fatigue with prolonged use. The photocurrent output decreases gradually during continued operation. Improved circuit design has helped to minimize fatigue effects.

4 VACUUM PHOTOTUBES

The vacuum phototube is an inexpensive photoemissive detector consisting of a semicylindrical cathode and a wire anode sealed inside an evacuated transparent tube. The concave surface of the cathode supports a photoemissive material (see Figure 1), which absorbs the incoming incident radiation. An electron may be released from the photoemissive material if the absorbed energy exceeds the photocathode work function. The emitted electron is directed towards the wire anode by the potential that is applied across the two electrodes. A current is generated by the resulting electron flow.

It should be noted that only a fraction of the photons striking the photoemissive material actually yield photoelectrons having sufficient kinetic energy to leave the photocathode surface. This is true even if the incoming photons have energies greater than the photocathode work function. The ratio of the number of photoelectrons ejected to the number of incident photons is referred to as the quantum efficiency, $Q_{\text{eff}}(\lambda)$. The quantum efficiency is wavelength dependent and typical values for most photoemissive materials range between $Q_{\text{eff}}(\lambda) = 0$ and $Q_{\text{eff}}(\lambda) = 0.50$. The rate at which photoelectrons are emitted from the photocathode, r_{cathode} (in s^{-1}), is found by multiplying the quantum efficiency by the photon flux of the incident radiation, $R_{\text{flux}}(\lambda)$, Equation (6)

$$r_{\text{cathode}} = Q_{\text{eff}}(\lambda)\, R_{\text{flux}}(\lambda) \tag{6}$$

Similarly, not all of the photoelectrons emitted are collected at the anode. The fraction that is collected is called the collection efficiency, CE_{anode}. The arrival rate of photoelectrons at the anode, r_{anode}, and the resulting anodic photocurrent, i_{anode}, are given by Equations (7) and (8), respectively

$$r_{\text{anode}} = CE_{\text{anode}}\, r_{\text{cathode}} = CE_{\text{anode}}\, Q_{\text{eff}}(\lambda)\, R_{\text{flux}}(\lambda) \tag{7}$$

and

$$i_{\text{anode}} = CE_{\text{anode}}\, r_{\text{cathode}}\, e = CE_{\text{anode}}\, Q_{\text{eff}}(\lambda)\, R_{\text{flux}}(\lambda) e \tag{8}$$

where e is the electron charge, $e = 1.6 \times 10^{-19}$ C. Both expressions contain wavelength-dependent quantities. If $Q_{\text{eff}}(\lambda)$ and $R_{\text{flux}}(\lambda)$ are not constant over the wavelength range incident upon the photocathode, then Equations (7) and (8) become integrals over the wavelength range. For most vacuum phototubes the anode current must be maintained lower than 10^{-5}–10^{-4} A in order to obtain a linear response.

Finally, vacuum phototubes do experience a small anodic dark current that typically ranges between 10^{-14} and 10^{-12} A. The dark current primarily results from thermal emission of electrons at the photocathode, which can occur at moderate bias voltages. Natural radioactivity from ^{40}K in the glass housing, ionization of residual gas, ohmic leakage, and field emission are additional sources of dark current in certain instances.

The theoretical treatment of vacuum phototubes is described in greater detail in a monograph devoted to spectrochemical analysis.[1]

From an operational standpoint vacuum phototubes are rarely used as fast detectors, except in those special instances that require the monitoring of low-repetition high-intensity sources. A nonexistent multiplier gain, combined with an average anode current slaved to the low cathode value, make accurate quantification of fast optical signals difficult.

5 PHOTOMULTIPLIER TUBES AND MICROCHANNEL PLATE PHOTOMULTIPLIER TUBES

The PMT is perhaps the most widely used of the different absorption and luminescence detectors. Not too many years ago PMTs were in almost every commercial UV-visible scanning and atomic absorption spectrophotometer, phosphorescence and flame emission spectrometer, and spectrofluorometer sold. Like the vacuum phototube, the PMT is a photoemissive detector which converts radiant energy directly into an electrical signal. Electrons are emitted from the photoemissive cathode surface when it is exposed to radiation. The tube contains additional electrodes (see Figure 4) called dynodes. The first dynode is maintained at a potential of 90 V or so more positive than the cathode. Electrons emitted from the photocathode are captured by the electrical potential and accelerated toward the first dynode (second electrode). Upon striking the dynode, each photoelectron causes emission of several additional electrons from the CuBe (or MgO, GaP, CsSb) alloy coating of the secondary electrode. These electrons in turn are accelerated toward the second dynode, which is at a 90 V potential more positive than the first dynode. Again, several electrons are emitted for each electron that strikes the dynode surface. The process is repeated at each of the n dynodes in the PMT. By the time that the electrons reach the anode, the original signal will have been multiplied by a factor of 10^3 (or more). Each incident photon ultimately results in 10^3 (or more) electrons being collected at the anode. Typical gains associated with PMTs used in commercial spectrophotometers vary from a lower limit of about $G \approx 10^3$ to an upper value of approximately $G \approx 10^8$.

In using PMTs, either the average current that is produced as a direct result of the arrival of the avalanched electrons or the number of anodic pulses per unit time can be measured. The latter measurement is referred to as photon counting even though charge packets, and not photons, are actually counted. The associated electron

Figure 4 Structures of the side window-type (a) and linear focused head-on-type (b) PMTs. For illustrational purposes, the threefold amplification is shown for only the first few diodes.

circuits in the photon counting mode measure the arrival rate of electrons at the anode, which is given by the mathematical expression in Equation (9)

$$r_{\text{anode}} = CE_{\text{fir dyn}} r_{\text{cathode}}\, G = CE_{\text{fir dyn}}\, G \int_0^{\infty} Q_{\text{eff}}(\lambda) R_{\text{flux}}(\lambda)\, \mathrm{d}\lambda \qquad (9)$$

where $CE_{\text{fir dyn}}$ is the fraction of the photoelectrons from the photocathode collected by the first dynode giving rise to the secondary electron emission. The PMT gain is denoted by G, $Q_{\text{eff}}(\lambda)$ refers to the quantum efficiency of the cathode's photoemissive surface, and $R_{\text{flux}}(\lambda)$ is the radiation flux incident upon the photocathode. For monochromatic (or nearly monochromatic) radiation, Equation (9) reduces to Equation (7) for the vacuum phototube, except for the fact that each anodic pulse now contains G electrons. The anodic pulse of a vacuum phototube contains only a single electron as the gain is unity (i.e. $G = 1$).

Figure 4 shows the structure of both the side window circular cage-type and linear focused head-on-type PMT. Both types of PMT are used in absorbance and luminescence measurements. A lower cost tends to make the side window tubes the detector of choice for routine absorbance and for steady state fluorescence measurements. For lifetime measurements there is no clearcut choice. Side window PMTs have a much faster instrumental response than commercially available linear focused PMTs. Kinoshita and Kushida[7] obtained an instrument response of 160 ps full width at half-maximum (fwhm) to a 10 ps mode-locked laser excitation. Bebelaar[8] reported an instrument response of 235 ps fwhm with a linear focused PMT. This is one of the faster instrument responses measured on a linear focused PMT. At this width it should be possible to determine fluorescence lifetimes experimentally down to $\tau_{fluor} \approx 30$ ps. Side window PMTs, with their much faster response times, are able to measure smaller fluorescence lifetimes. It should be noted that in order to obtain the faster pulses, it is necessary to irradiate only a very small area of the side window PMT's photocathode. This requirement does restrict the sensitivity of the measurements to a level which can only be tolerated when using mode-locked laser excitation.

If instrument response time were the only consideration, then a side window PMT might be the detector of choice for time-resolved fluorescence measurements. One of the advantages afforded by linear focused PMTs is a slower transit time dependence on the point of photocathode illumination. Commercial linear focused PMTs have a transit time dispersion of about 13 ps mm^{-1}.[9] With a linear focused PMT there is no need to sacrifice sensitivity by reducing the illuminated area in order to obtain the maximum time resolution. The spectral ranges of side window and linear focused PMTs are comparable.

Determination of fluorescence lifetimes requires a minimum fast time response of 1.5 ns (or less) risetime. In PMTs the risetime originates from the distribution in anode arrival times of the avalanched electrons produced by simultaneously triggered photocathode events. A distribution in arrival times results because the ejected electrons have different energies and the electrons take slightly different pathways in traveling to the next anode. A single electron emitted at the photocathode will yield a several nanosecond distributed current pulse by the time the event is finally detected at the anode.

Manufacturers have been successful in reducing the risetime by replacing the early unfocused box-and-grid and venetian blind photocathode–anode configurations by the circular cage and in-line designs shown in Figure 4. Planar cathodes, which can have edge-to-center transit time differences as large as 10 ns, have been replaced by curved photosensitive surfaces. The two aforementioned modifications have helped to reduce the risetime of the PMT to 1–2 ns. The risetime can be further reduced by utilizing dynode materials such as GaP which emit more secondary electrons when impacted by a high-energy electron. The new GaP coatings can emit as many as 50 electrons per each electron impact, i.e. $\Gamma = 50$. This allows the total number of dynodes to be reduced, while still maintaining the high gains necessary to detect low levels of incident radiation. Several commercial PMTs employ a GaP coating for only the first dynode. For such PMTs, the gain achieved by the detector is given by $G = \Gamma_{GaP}\ (\Gamma_{other})^{n-1}$, where $n - 1$ represents the number of non-GaP dynodes in the PMT.

In addition, modern PMTs impose high electric field strengths at the dynode surfaces and use crossed electric and magnetic field strengths to control the pathway the electrons take to reach the next dynode better. The above modifications have enabled construction of PMTs having ~150 ps risetimes. From an operational point of view, the detector should have a risetime that is short compared to the variation in the signal being measured. As a rule-of-thumb, the risetime should be one-tenth (or less) of the variation in the measured signal.[3]

Fast instrument responses and fast risetimes are important considerations in detector selection for time-resolved studies. In certain instances involving single photon events it might be possible to reference measurements to some fixed point on the resultant output pulse. A fast risetime is no longer as important if a reference point is used. Detector selection then becomes governed more by the time jitter of the anodic pulse maximum for repeated equivalent events. The variation in transit time follows roughly a Gaussian distribution, with the width being one-quarter to one-third that of a delta-function response pulse. Anode jitter time can be extremely sensitive to the extent of optical coverage afforded by the photocathode.[3]

Dark currents in PMTs result from the thermal emission of electrons at the photocathode surface, ionization of residual gas, natural radioactivity from ^{40}K in the glass, ohmic leakage and thermal emission of electrons from the dynodes. The first four sources were identified previously as causes of dark current in vacuum phototubes. Dark currents in PMTs typically are in the range of 10^{-11}–10^{-7} A. Thermal emission of electrons from the photocathode (or early dynodes) are multiplied by the full gains of the PMT. The amplification leads to the much larger dark current of the PMT, compared with the 10^{-14}–10^{-12} A dark current for vacuum phototubes.

In early analytical applications PMTs were used to monitor radiation in both the UV and visible spectral regions. The majority of photoemissive materials listed in Figure 1 have their maximum sensitivity somewhere in the 200–600 nm wavelength region. In the vacuum UV, from about $\lambda \approx 30$ nm to $\lambda \approx 190$ nm, the sensitivities of the photoemissive materials in Figure 1 are generally quite

low. Radiation can be successfully detected, however, by adding a fluorescing plate (sodium salicylate on a Pyrex window) as a converter in front of the PMT. Whenever radiation strikes the added window, the compound fluoresces at about 400 nm, leading to a reasonably linear PMT signal across the cited spectral range. For many years the best IR sensitive photocathode material was Ag/O/Cs, denoted as S-1 in Figure 1. The modest quantum efficiency, $Q_{\text{eff}}(\lambda)$, of Ag/O/Cs may explain why very few red and near-IR (600–1000 nm) fluorescence measurements were made until just recently. Most photoemissive detectors lacked sensitivity in this spectral region. Red and near-IR fluorescence measurements are now possible using PMTs equipped with a In/Ga/As (Cs) photocathode, which offers improved performance out to $\lambda = 1010$ nm and a dark current 100 times smaller than the S-1 photocathode.[10]

Microchannel plate photomultiplier tubes (MCPPMTs) have been around for several years. It was not until recently, however, that the detector made an impact in fluorescence lifetime studies. Electron magnification occurs as electrons travel between thin glass plates through the many microscopic channels. Each channel is lined with a secondary emitting surface and functions as an individual electron multiplier. The glass surfaces of each plate between channels are coated with a thin nichrome (or other conducting material) layer and a large voltage (~1000 V) is applied across the thickness of the plate to direct the flow of electrons toward the anode. Figure 5 depicts a MCPPMT with three plates.

Figure 5 Schematic diagram of a MCPPMT detector (top), depicting the hexagonal arrangement of the plate's microchannels. The bottom drawing shows the electron amplification which takes place in the individual microchannels when electrons strike the secondary emitting surface.

The MCPPMT operates in the following fashion. A photoelectron emitted from the photoemissive surface of the photocathode when exposed to incident radiation is accelerated a short distance (approximately 3 mm) to the first microchannel plate (MCP). The photoelectron enters one of the channels of the plate where it eventually strikes the wall producing secondary electrons. These electrons in turn are accelerated further down the channel and additional collisions occur. On the average between one and three secondary electrons are released per collision. Upon exiting the channel, the electrons spread out and enter a number of adjacent channels in the second MCP (see Figure 5). Further multiplication occurs in the second and in each succeeding MCP. Spatial information is maintained since the secondary electrons are confined within the microchannels. After the electron cascade passes through the last plate it is finally collected at the anode as a pulse of current.

MCPPMTs are more compact than conventional PMTs, and as a result electrons travel much shorter distances. The more compact design leads to both faster time responses and less fluctuation in the length of time between the release of the first photoemissive photoelectron and its subsequent detection as an anodic current pulse. Risetimes of 150 ps and a transit-time jitter (i.e. impulse response) of approximately 25 ps fwhm at 200 counts s^{-1} noise at ambient room temperature have been recorded with a commercial 6-μm channel MCPPMT.[11] The compact design of the MCPPMT makes it amenable to cooling. Each MCP can provide, depending upon length and secondary emitting surface, electrons gains of 10^3–10^4 over an active diameter of more than 30 mm with an electron equivalent input noise of 10^{-16}–10^{-15} A cm^{-2}. When placed in tandem, as would be the case with a MCPPMT, combined MCP can give gains of $G = 10^6$ to $G = 10^7$, which are comparable to those obtained with conventional PMTs.[12]

6 PHOTODIODE AND PHOTODIODE ARRAY DETECTORS

Photodiode absorbance detectors operate differently from the vacuum phototubes and PMTs that were just discussed. In a photodiode the incoming radiation promotes electrons from the valence band to the conduction band of a semiconducting material, as opposed to releasing electrons from a photoemissive surface. A semiconductor is a crystalline material having a conductivity between that of an insulator and a conductor. Crystalline silicon and germanium are the two semiconducting materials that have found widest application in the construction of electronic devices. Both elements are in group 14 of the periodic table and thus have four valence electrons for

bond formation. All four valence electrons are localized in the silicon/germanium crystal through covalent bonding with neighboring atoms. In theory, silicon and germanium should behave as insulators since there are no free electrons in the crystalline lattice. Sufficient thermal agitation occurs at ambient room temperature, however, to liberate an occasional covalently bonded electron. The liberated electron is free to move about the crystalline lattice to conduct electricity. Thermal excitation also leaves a positively charged region where the liberated electron once resided. The positively charged region, referred to as a hole, is also mobile in that a bound electron from a neighboring Si (or Ge) atom jumps to the electron deficient region and in turn leaves behind a hole. Conduction in a semiconductor involves movement of thermal electrons in one direction and holes in the other direction.

The conductivity of a Si (or Ge) crystal can be enhanced by judiciously adding a small controlled amount of group 13 or group 15 impurity. Replacement of a silicon atom with a group 15 element (As or Sb) introduces one unbound valence electron into the structure (see Figure 6). Very little thermal energy is needed to free this extra electron for conduction of electricity. A Si (or Ge) crystal that has been doped with a group 15 element is referred to as an n-type semiconductor. Electrons are the majority charge carriers. Holes still exist as the result of thermal agitation of silicon atoms; however, their number is small compared to the number of electrons. Similarly, a p-type semiconductor is formed whenever a Si (or Ge) crystal is doped with a trivalent group 13 (In or Ga) element. An electron deficiency exists at each place where In (or Ga) is inserted. Holes are created in the crystalline lattice whenever covalently bonded electrons from neighboring Si (or Ge) atoms move to the vacant orbital associated with the group 13 impurity atom. Movement of holes from one Si (or Ge) atom to another, as described above, leads to a current in which the majority carrier is positive. A p-type semiconductor is inherently less conductive than a n-type semiconductor. Holes are less mobile than free electrons.

A photodiode is formed by having adjacent p-type and n-type regions within a single silicon or germanium crystal. Close proximity of n-type and p-type materials permits movement of holes from the p-region into the n-region and movement of electrons in the opposite direction. When the diode is reversed-biased (see Figure 7) the majority carriers in each region drift away from the junction to form a depletion layer, which contains few charges. Essentially no current flows in the absence of electromagnetic radiation. When photons strike the semiconductor, electrons are promoted from the valence band to the conduction band where they act as charge carriers. The current that is produced is proportional to the incident light intensity.

Photodiodes are used as absorbance detectors to monitor radiation in the UV-visible and near-IR spectral regions. The spectral response of most photodiodes

Figure 6 Representation of a n-doped (top) and a p-doped (bottom) silicon crystal. Valence electrons and holes are denoted by the solid circles (●) and open squares (□), respectively.

Figure 7 Schematic diagram of a silicon diode operated under reversed bias. Movement of electrons and holes away from the pn junction leads to the formation of a depletion layer.

reaches a maximum in the near-IR spectral region ($\lambda = 800-1000$ nm). These devices exhibit excellent linearity over six to seven decades of incident radiation power. Photodiodes have subnanosecond response times. Design simplicity and small size, combined with the performance characteristics listed above, have made photodiodes a very popular detector for analytical applications where light levels are relatively high.

MCPs have been used in several instances to intensify signals prior to detection by a photodiode detector. These devices operate in similar fashion to the MCPPMTs, except that the electrons upon exiting the MCP are now accelerated towards a phosphor screen. The resulting photons are coupled with a fiber-optic bundle to the photodiode. The photodiode monitors the photon bursts at the phosphor screen. MCPs are designed to provide a 10^3-10^4 gain prior to detection by a silicon photodiode. Bormett and Asher[13] reported that diffraction can pose problems when using MCP intensifiers. Diffraction redirects a fraction of the spectrophotometer-dispersed radiation back into the instrument, where it may be reflected or scattered from other optical components and later reimaged onto the detector.

Avalanche photodiodes (APDs) are used in analytical applications, such as single-photon timing and phase fluorometry,[14–24] which require both a fast response and high sensitivity. These devices are operated in the reversed-biased breakdown region of the pn junction and provide an internal gain of up to $G = 1000$. The electron–hole pairs produced by the impinging incident radiation create additional pairs in an avalanche effect. Careful control of the bias voltage is required in order to obtain the stable current gains needed for accurate measurements. Response times do depend upon the internal gain. Very fast instrumental response widths as low as 70 ps fwhm have been reported for single-photon timing experiments.

Silicon single-photon APDs provide excellent responsivity down to wavelengths of $\lambda = 1000$ nm. Germanium (Ge) and InGaAs photodiodes are used to monitor longer wavelengths (see Figure 2). These semiconductors have relatively high quantum yields; however, they do give fairly noisy signals at ambient room temperature. This is particularly true in the case of Ge semiconductors. PDA detectors used for near-IR studies are often cooled to below room temperature in order to reduce the noise. The noise problem is further addressed by minimizing the photodiode active area as much as possible. Noise is proportional to the active surface area. Areas of less than 1 mm^2 are required to achieve subpicowatt noise levels. In the case of single photon APDs, the surface areas are typically in the neighborhood of 10 μm in diameter. The small active surface area significantly reduces the detector's sensitivity, to the point where a microscope and/or high-powered laser source may be needed for accurate quantification. It should also be noted that APDs can exhibit a wavelength-dependent tail in their response due to charge carriers generated in the neutral p-region beneath the depletion layer. The tail becomes more pronounced at longer wavelengths and can hinder reconvolution analysis of single-photon timing experiments.[14]

Since the late 1970s rapid advances in semiconductor-based technology and the related development of powerful microprocessor systems led to the evolution of numerous multichannel absorption and luminescence detectors. Multichannel detectors enable the analyst to acquire a large amount of spectrally and/or spatially resolved data in a single observation. The linear photodiode array (LPDA) detector consists of an array of photodiodes (also called elements, channels and pixels). Each photodiode acts as a separate photon-to-charge transducer and a charge storage device. Linear arrays designed for commercial UV-visible spectrophotometers are spaced on 25-μm centers and have apertures of 2.5 mm. This particular design gives an aspect ratio of 100 : 1, which corresponds to the typical aspect ratio of a conventional UV-visible scanning spectrophotometer or polychromator slit. A reversed-biased pn semiconductor diode serves as each photosensitive element. Readout is performed by a shift register operating in real-time, variable integration, diode group or "skipping-diode" mode. Commercial units read out and digitize the diode information at rates from 4–28 ms per photodiode. The various readout modes are reviewed in a two part series devoted to PDA detectors in UV-visible spectroscopy.[25,26]

Figure 8 depicts a LPDA being operated under reversed bias. The PDA consists of p-type bars diffused

Figure 8 Diagram of the LPDA showing reversed bias pn junction with diffused p-type bars in the n-type silicon substrate. (Redrawn with permission from D.G. Jones, *Anal. Chem.*, **57**, 1057A–1073A (1985). Copyright American Chemical Society.[25])

into a n-type silicon substrate. Both semiconductor types are photosensitive. The capacitive diode is fully charged at the beginning of each measurement cycle. Electron–hole pairs form upon irradiation. Charges generated from light incident on the areas between diodes (i.e. between p-regions) divide proportionally between adjacent diodes. Photogenerated electron–hole pairs separate in the electric field, with the electrons and holes drifting to the positively charged cathode and negatively charged anode, respectively. A leakage current flows if the diode remains connected to the voltage source. This current is proportional to the photon flux incident on the diode. If the diode were to be disconnected from the voltage source, then the electron–hole pairs will discharge the potential previously stored. The photon flux incident upon the diode is found by measuring the current needed to recharge the diode to its original value, or by measuring the resulting change in potential across the diode.

PDAs are available commercially in both linear and area formats. Linear PDA are useful for monitoring radiation in the 200–1000-nm spectral region. Two-dimensional PDAs have found application in analytical chemistry for measuring radiation in the near- and mid-IR regions. Long-wavelength materials, such as HgCdTe, InSb and InGaAs (see Figure 2) allow measurements to be made down to a wavelength of $\lambda = 1800$ nm (or longer). Two-dimensional PDAs can either be used for direct wavelength detection on the focal plane of a spectrograph, or used in conjunction with a modulated radiation source to generate chemical specific maps of a sample.[2]

Parameters that govern the overall performance of PDA spectrophotometers include dynamic range and precision, spectral resolution, S/N, level of stray radiation and sensitivity. These parameters are determined to a large extent by the photodiode size and spacing. As a general rule-of-thumb, the dynamic range increases with increasing diode size, whereas greater resolution is obtained with the narrower photodiodes. The photodiode dimensions that match the spectrophotometer slit offer the best compromise for maximum resolution and dynamic range. Linear PDAs inside of commercial UV-visible scanning spectrophotometers have a spectral resolution of ± 1 nm in the UV spectral region (200–400 nm) and ± 2 nm in the visible range (400–800 nm). PDA detectors designed for spectroscopic applications have a dynamic range of about 10^4 for single integration time,[27] which is over two orders of magnitude smaller than can be obtained with a PMT. The linear dynamic range of a LPDA is in general lower than that of a single photodiode. (A single photodiode exhibits linearity over six to seven decades of incident radiation power.) The lower dynamic range results from internally reflected light from the window, the silicon wafer and spectrophotometer's metallic parts. Finally, PDAs do benefit from the Fellgett advantage in that the entire analysis time is spent making measurements at all wavelengths. The largest signal is obtained whenever the time between readouts is increased until the signal is just below saturation (i.e. integrate the signal on-chip). On-chip integration increases the S/N proportionally to the exposure time, as opposed to the square root of the accumulated exposure time in the case of conventional ensemble average.[25]

The quantum efficiency, Q_{eff}, of a PDA is quite high; however, the recharge process is quite noisy and may result in a readout noise of greater than 1000 electrons. A large readout noise significantly degrades S/Ns for weak signals. In analytical chemistry PDAs are generally used in applications, such as absorption spectroscopy, where illumination levels are high. PDA detectors (without intensifiers) are virtually useless in Raman spectroscopy because the readout noise overwhelms the weak scattering signal. Also, the dark current signal can be fairly large due to capacitor leakage, which would preclude S/N improvements based upon longer integration times. To apply the PDA to Raman spectroscopy successfully, the signal must be amplified significantly above both the readout and dark noise. MCPs have been used to boost weak Raman scattering signals for subsequent PDA detection, with only slight degradation of spatial resolution being observed. The MCP is placed prior to the PDA. Electrons exiting the MCP hit a phosphor screen and the PDA monitors the resulting photon bursts. MCP itensified PDAs have a major advantage when time resolution is required. The MCP can be switched on and off quickly. Although the PDA is integrating the signal during the entire time between readouts, the intensifier gain is so large that only the photons arriving when the MCP is on are counted. The ''contrast ratio'' between gate on and gate off signals is typically 10^6 (or larger).

Linear PDAs have completely revolutionized absorbance detection in high-performance liquid chromatographic (HPLC) separations. Analysts now obtain multiwavelength chromatograms from a single injection, which decreases the analysis time and facilitates both solute identification and quantification. In cases where the solutes are not resolved by the column but where spectral overlap is minimal, it is possible to determine the concentration of all components within a single elution profile by judiciously monitoring each component at wavelength(s) that are free of interference. One can select between the wavelength of maximum absorbance to achieve greater sensitivity, or the wavelength giving the optimum signal relative to possible interferences if greater selectivity is desired. Prior to LPDAs, several injections would be needed to obtain the same information. The output intensity from several discrete photodiodes can be summed to increase the detectability by a factor of

five-fold to 500-fold. Moreover, simultaneous data acquisition at different wavelengths also ensures the detection of most mixture components. The applicability of LPDAs in HPLC is described in several review articles.[26,28,29]

7 CHARGE TRANSFER DEVICES

PDAs do not offer the sensitivity, dynamic range, linearity and noise performance to be competitive with PMTs in many analytical applications. PDAs are used primarily in those applications where a broad spectral region needs to be monitored simultaneously (e.g. kinetic studies, HPLC detection). Here, the multichannel advantage outweighs the noise, cross talk and limited sensitivity and dynamic range shortcomings of PDAs. Recent advances in solid state and semiconductor technology have led to new multichannel detectors incorporating charge transfer devices (CTDs), which have performance characteristics comparable to commercial PMTs. Hanley et al.[30] derived mathematical formulas describing CTD performance with regard to minimum and maximum detectable absorbance, maximum S/N and maximum dynamic range for absorbance and luminescence measurements.

CTD is a generic term given to two types of related solid state radiation detectors, the CCD and the charge injection device (CID). The CCD was co-invented by Willard Boyle and George Smith in 1969. These two individuals, who were employees of Bell Laboratories, wanted to develop a silicon diode for a picturephone. They devised a method for passing charge from one capacitor to another by changing an applied voltage in a coordinated fashion. This idea led to the CCD, which was subsequently constructed and tested at Bell Laboratories. Three years later Gerry Michon and Hugh Burke, employees at General Electric Company's corporate research center, built the first CID by placing two adjacent metal-oxide semiconductor (MOS) capacitors on the edge of a wafer of an experimental device. This construction was found to be light sensitive. The historical development of both CCDs and CIDs is reviewed in greater detail elsewhere.[31]

The MOS capacitor is an important component of CTDs. A MOS capacitor consists of a gate electrode overlying insulating, epitaxy and substrate layers. The substrate is crystalline silicon (~0.5 mm thick for mechanical support) which has been highly doped with either a group 13 (p-type, CCDs) or a group 15 (n-type, CIDs) element for electrical conductivity. The gate electrodes are made of a semitransparent, highly polycrystalline silicon material. The epitaxy is a thin lightly doped region that forms the photoactive region of the MOS capacitor. The epitaxy is p-doped for CCDs and n-doped for CIDs. Insulating silicon oxide and nitride layers separate the epitaxy from the gate electrode structures. The gate and epitaxy form the two capacitor plates.

CTDs operate much like a photographic film in that they integrate signal information when irradiated. The basic operation of a CTD detector can be illustrated using Figure 9, which depicts the cross-section of a single pixel of a CTD in the charge integration mode. In this case, the pixel consists of two conductive electrodes that overlie an insulating layer of silicon oxide. The silicon oxide layer separates the electrodes from a region of n-doped silicon. Electrons are the majority charge carrier for this example. When the two electrodes are negatively charged with respect to the silicon, a charge inversion layer is created under each electrode. The mobile holes created by the absorption of photons migrate and collect under the electrodes. This region, called a potential well, is capable of holding up to 10^5–10^6 charges before overflow to an adjacent pixel (referred to as blooming). As shown in Figure 9 the right electrode is maintained at the more negative potential. Positive charge thus accumulates under the right electrode. The amount of charge in a CTD detector during exposure to radiation can be measured in one of two ways. First, in a CCD the charge is moved to a charge-sensing amplifier for measurement. Alternatively, the voltage change that results from movement of the charge from the region under the right electrode to the region under the left electrode can be measured. The latter measuring mode is used in CIDs.

Figure 10 shows how cycling of gate potential sequentially shifts a charge packet from gate to gate to move it across the CCD. Note a CCD collects photogenerated electrons, rather than holes, under the electrodes as the

Figure 9 Cross-section of a CTD detector element when the electrodes are biased for charge integration. (Redrawn with permission from J.V. Sweedler, R.B. Bilhorn, P.M. Epperson, G.D. Sims, M.B. Denton, *Anal. Chem.*, **60**, 282A–291A (1988). Copyright American Chemical Society.[32])

Figure 10 Pictorial diagram of a CCD. The left frame illustrates how cycling of gate potential sequentially transfers a charge packet from one gate to another. Three such transfers are needed to move the charge across a single pixel. The right frame shows how charge is transferred from pixel to pixel in the parallel register into the serial register and then to the readout amplifier. The shaded area in the upper right hand corner corresponds to one pixel. (Redrawn from J.M. Harnly, R.F. Fields, *Appl. Spectrosc.*, **51**, 334A–351A (1997). Copyright Society for Applied Spectroscopy.[2])

silicon substrate is doped with a p-type impurity. The device depicted in Figure 10 has three-gate pixels and a three-phase architecture, i.e. three transfers are required to move the charge across a single pixel. First, the charges in the vertical registers (referred to as the parallel shift register) are shifted downwards one register. The charges that were shifted into the horizontal register (also called the serial shift register) are then transferred sequentially into a summing well and then to a readout amplifier. Once the serial register is emptied, the entire process begins again with another vertical shift, and continues until all of the pixels are emptied.

Charge blooming is the leakage of accumulated charge from an illuminated detector element to adjacent elements. The onset of blooming in a CCD occurs whenever the maximum number of photogenerated charge carriers that can be held in an element is exceeded. Channel stops in the parallel shift register prevent charge blooming across columns and as a result the bloomed charge spills down the column. Manufacturers now offer CCDs with antiblooming drains, which accumulate and transport away the excess photogenerated charges. These CCDs generally exhibit slightly lower quantum efficiencies. Part of the area is taken up by the antiblooming drain.

CCDs are currently being used in UV-visible absorption, fluorescence and Raman spectroscopies, where measurements might require the long integration of low intensity radiation. Epperson et al.[33] reported a detection limit of anthracene of 1 ppt at S/N = 2 based upon fluorescence measurements with a relatively weak 35-W deuterium lamp excitation source. The reported detection is an order of magnitude lower than that determined using a high-powered tunable dye laser excitation source.[34] Murray and Dierker[35] studied monolayers of organic sorbates of different substrates by unenhanced Raman spectroscopy. The authors reported a S/N = 15 when measuring the monolayer coverage of cadmium stearate films deposited on glass and silicon surfaces with a CCD. Zhao and McCreery[36] successfully demonstrated the applicability of a CCD as a radiation for Fourier transform (FT) Raman spectroscopy in the near-IR region. Measurements revealed that the common path interferometer-CCD spectrometric system possessed many of the advantages inherent to FT

spectroscopy (e.g. high throughput, excellent frequency precision and wide spectral coverage) and CCD detection (shot-noise limited operation). The observed S/N of the multichannel FT system was comparable to that for a dispersive spectrometer for the same laser power and integration times.

Modified CCDs have been used in conjunction with an echelle grating inductively coupled plasma emission spectrometer to study samples containing up to 72 different elements. The detector, called a segmented array charge-coupled device (SCD), consisted of 224 linear CCDs imbedded into a monolithic silicon block. The light beam originating from the torch is split by a Schmidt cross-disperser. Cross-dispersed radiation is focused onto an SCD for intensity measurements in the UV spectral region (160–375 nm). The undispersed radiation is passed through a prism for cross-dispersion and subsequently focused onto a second SCD for intensity quantification in the visible (375–782 nm). Each array segment can be addressed separately and the charge integration time can be varied over a wide enough range to provide dynamic ranges of 10^5 or greater.[37,38]

CIDs operate in a similar fashion, except for the method of measuring the charge accumulated under the electrode. Each pixel of a CID is defined by the intersection of a row and column gate electrodes as shown in Figure 11. At the beginning of a measurement period negative potentials are applied to both electrodes, which leads to the formation of potential wells that collect and store holes formed in the n-doped silicon substrate by absorption of photons. Holes preferentially migrate to the collection gate because of its more negative potential. Excess charge rarely spills over into adjacent elements. After integration (or the end of the measurement time), each pixel is read using correlated double sampling. The potential gate for the sense gate is disconnected and the potential read (step B in Figure 11). The holes that have accumulated under the collection gate are then transferred to the sense gate by changing the potential applied to the collection gate from negative to positive. The new potential of the sense gate is measured. The difference between the two potential readings is proportional to the charge collected in the well. After the pixel is read, the charge may be either injected into the silicon substrate by raising the gate potential and collapsing the well (step D in Figure 11), or returned back to the collection gate by restoring its original negative potential in a nondestructive readout (NDRO). The NDRO is often used in CIDs to reduce random noise and to extend the dynamic range of the sensor. A major advantage that CIDs have over CCDs is that successive measurements can be made while integration is still taking place.

Published articles[39–41] have also reported that two-dimensional CID array detectors can be used in an echelle

Figure 11 Pictorial representation illustrating the operation of a CID. Top frames A–C show how the sense and collection gates accumulate charge for both a destructive readout (DRO) and NDRO. The bottom frame shows the random access of pixels with column and row gates. (Redrawn from J.M. Harnly, R.F. Fields, *Appl. Spectrosc.*, **51**, 334A–351A (1997). Copyright Society for Applied Spectroscopy.[2])

spectrometer for direct current and inductively coupled plasma atomic emission spectroscopy. Dark currents in the detector elements are minimized by housing the unit in a liquid nitrogen cryostat maintained at a temperature of 135 K. Two-dimensional CID arrays possess the necessary number of resolution elements for measuring hundreds of emission lines and surrounding background. Analysis of complex samples requires that several emission lines and associated background regions be measured for each element in order to reduce errors arising from matrix effects. The preceding examples describe only a few of the many published applications where either a CCD or CID was used. CTDs have been used as absorbance and luminescence detectors in nearly all areas of analytical chemistry including molecular luminescence,[33,42] atomic

emission spectroscopy,[37–41] Raman spectroscopy,[35,36] X-ray diffraction,[43,44] microscopy[45] and chemical separations.[46]

8 STREAK TUBES AND STREAK CAMERAS

The streak camera is a device that converts time information from a luminous event into spatial information. Streak cameras are capable of measuring fast optical signals. There are two general types of streak cameras, the mechanical and the image convertor. In the mechanical version the signal is swept quickly across a piece of photographic film by a high-speed rotating mirror. Typical performance characteristics would be 2–100-ns resolution and a 15–800-ms time window.[3] In the image convertor (Figure 12) electrons emitted from the photocathode upon irradiation are extracted by the grid and accelerated at high velocity toward the anode. After passing through a hole in the anode the electrons are deflected by the voltage ramp applied to the deflection plate. The voltage ramp increases in strength with increasing time. A MCP intensifier may be used to multiply the number of electrons prior to detection. Upon exiting the MCP, the electrons strike a phosphor screen. The result of the aforementioned processes is that the time dependence of the radiation intensity is translated into the distance dependence of electron impact upon the phosphor screen. The shape of the voltage ramp used to deflect the electrons determines the relationship between time and impact distance. Photon bursts from the phosphor screen can be photographed with a normal camera, or sent to a CCD for quantification. Image convertors have time resolutions of 0.1–20 ps. The main advantage that streak cameras have enjoyed over photon counting methods has been time resolution. Streak camera time resolutions of 0.5 ps fwhm (or less) are obtainable. The best time-resolved single-photon counting methods, employing fast MCPPMTs, are about two orders of magnitude longer in fwhm.

Figure 12 Diagram of a streak tube, which is the heart of the streak camera system. The MCP (not required) multiplies the number of electrons prior to their impact on the phosphor screen. A streak camera system would also include the camera or CCD for recording the photon bursts.

Many of the early streak cameras were plagued by time and intensity nonlinearity, flyback artifacts and a limited dynamic range. Manufacturers have now overcome many of these problems with improved designs. Streak cameras were designed to measure the time dependence of light emitted by a sample. Several of the processes that can be monitored include: protein binding reactions (0.1 ps to 1 ms); energy transfer in proteins (<1 ps to 100 ps); rotational diffusion (<1 ps to >1 ns); excited state proton transfer (<10 ps to >100 ps); electronic relaxation (<1 ps to 100 ns); and exciplex formation (<10 ps to 10 ns).[47,48] The corresponding timescales, picoseconds (ps) to milliseconds (ms), are given in parentheses. Several of these processes can also be monitored with absorption spectroscopic methods.

9 THERMAL DETECTORS

Thermal detectors, which are used in the IR region, sense the change in temperature that results from the absorption of incoming incident radiation. Thermal detectors are made of low heat capacity materials as the radiant power level from a typical IR beam is small (in the range of 10^{-9}–10^{-7} W). The size and thickness of the absorbing element is minimized as much as possible and every effort is made to focus the entire IR beam onto the detector surface. Thermal detectors are housed in a vacuum and carefully shielded inside the spectrometer. The beam from the radiation source is generally chopped to minimize further the undesired efforts of extraneous heat. The analyte signal would then have the frequency of the chopper and could easily be distinguished from extraneous noise, which would vary slowly with time.

The first of the thermal detectors to be considered is the thermocouple, which consists of a pair of junctions formed whenever two identical pieces of metal (e.g. Bi) are fused to each end of a dissimilar metal (e.g. Sb). One junction serves as a reference of "fixed" temperature, while the second junction becomes the sensor for IR radiation. (Note, the reference junction does not need to be maintained at constant temperature if the analytical signal is chopped.) The sensing transducer junction is normally blackened to improve its heat-absorbing capacity and sealed in an evacuated chamber

having a window made from a material that is optically transparent to IR radiation. The reference junction is designed to possess a relatively large heat capacity and is carefully shielded from the incident radiation. A potential develops between the two junctions that varies with the difference in temperature of the junctions. A well-designed thermocouple IR detector is capable of responding to temperature differences as small as 10^{-6} K. The thermocouple detector has uniform spectral response in the 1–40-μm wavelength region, excellent linearity and reasonable sensitivity. The detector's sensitivity can be further enhanced by connecting several thermocouples in series. Now, the output potential is the sum of the potentials across the individual thermocouples. Multiple thermocouple devices are referred to as thermopiles. Thermocouple detectors are used in dispersive mid-IR spectrometers.

IR radiation can also be detected with thermistors. These detectors are constructed from intrinsic semiconductor materials that exhibit relatively large changes in resistance as a function of temperature. The responsive element is again kept small and blackened to absorb radiation. The thermistor is generally placed in a bridge circuit (e.g. Wheatstone bridge) with a reference thermistor that is not irradiated. The resistance can be measured by a null-comparison technique, or the out-of-balance voltage of the bridge can be monitored. Thermistors exhibit moderate sensitivity and a wide linear range.

Thermocouples and thermistors respond considerably slower than PMTs, CCDs, CIDs and photodiodes because time is required for the temperature of the element to change. Typical response times for thermocouples and thermistors are in the range of 0.01–0.1 s. Such response times are much too slow for FT spectroscopy. Commercial Fourier transform infrared (FTIR) spectrometers use pyroelectric or Golay detectors, which exhibit responses that are fast enough to track the changes in the time-domain signal from an interferometer.

Pyroelectric detectors are constructed from single crystalline wafers of pyroelectric materials, such as triglycine sulfate (usually deuterated with a fraction of the glycines replaced with alanine), lithium niobate ($LiNbO_3$) or lithium tantalate ($LiTaO_3$). Pyroelectric substances exhibit a large spontaneous electrical polarization at temperatures below their Curie point, which in the case of triglycine sulfate is 47 °C. ($LiNbO_3$ and $LiTaO_3$ have higher Curie points and do not exhibit hygroscopicity, which is sometimes a problem encountered with triglycine sulfate.) If the temperature of a pyroelectric material is changed, then the degree of polarization is changed. The change in polarization can be quantified by placing the pyroelectric crystal between two electrodes to form a capacitor. When the polarization changes, the charges induced on the electrodes create a measurable current in an external electric circuit that connects the two sides of the capacitor. The output current is proportional to the surface area of the crystal and to its rate of change of polarization with temperature. Pyroelectric detectors have fairly fast response of less than 1 ms over most of the IR region encountered in analytical chemistry. For wavelengths below 2 μm, the triglycine sulfate must be blackened to enhance photon absorption. This can slow the detector's response. Linear arrays of pyroelectric detectors are also available.

It should also be noted that thermocouples, thermopiles and pyroelectric devices have also been utilized in conjunction with electrical substitution radiometers in absolute photon flux measurements.[49] The detector is a thermal sensor in contact with a good absorber of radiation and an electric heater. Photons are absorbed by the thermal sensor and the detector output, $T_{\text{radiation}}$, is read. The radiation source is then shuttered to prevent light from reaching the detector. Once the sensor returns to its original temperature electric power is applied to the heater until the detector's output reaches $T_{\text{radiation}}$. Measurement of the electric power when $T_{\text{electric}} = T_{\text{radiation}}$ yields the equivalent of the radiant power absorbed. Sensitivities of electrically calibrated pyroelectric radiometers range from 100 mW down to 100 μW full scale.

Golay detectors can be used in FTIR spectrometers having slow-scanning and/or stepped-scan interferometers. Figure 13 depicts a Golay cell, which is essentially an airtight pneumatic chamber filled with a gas of low thermal conductivity (e.g. xenon). The chamber is closed at one end by a thin rigid blackened metal plate and by a flexible silvered diaphragm at the other end. Radiation passes through a small IR-transmitting window and is absorbed by the blackened plate. Heat, conducted to the gas, causes it to expand and distort the flexible

Figure 13 Schematic diagram of a Golay cell.

diaphragm. A fine leak connects the detection chamber to a ballasting reservoir of gas to prevent ambient room temperature changes from affecting the measurement. Light from a tungsten filament lamp is focused upon the silvered diaphragm and is reflected back to a PMT (or other suitable radiation detector). Distortion of the silvered diaphragm moves the light beam across the PMT surface and changes its electrical output. Golay detectors are considerably more sensitive than thermocouples. Response times are typically on the order of 20 ms. Golay detectors may be used only with slow-scanning or stepped-scan interferometers, and where the IR radiation is modulated by an external chopper. Radiation modulated in the audiofrequency regime must be detected by either pyroelectric detector or semiconductor detector (e.g. PbS, PbSe and HgCdTe).[50] As noted previously, semiconductor detectors can be operated in either the photovoltaic or photoconductive model. The approximate spectral ranges of the various semiconductors used in commercial absorption and luminescent detectors are given in Figure 2. This list will undoubtedly grow in number in future years as new semiconducting materials are produced and tested.

ABBREVIATIONS AND ACRONYMS

APD	Avalanche Photodiode
CCD	Charge-coupled Device
CID	Charge Injection Device
CTD	Charge Transfer Device
FT	Fourier Transform
FTIR	Fourier Transform Infrared
fwhm	full width at half-maximum
HPLC	High-performance Liquid Chromatographic
IR	Infrared
LPDA	Linear Photodiode Array
MCP	Microchannel Plate
MCPPMT	Microchannel Plate Photomultiplier Tube
MOS	Metal-oxide Semiconductor
NDRO	Nondestructive Readout
PDA	Photodiode Array
PMT	Photomultiplier Tube
SCD	Segmented Array Charge-coupled Device
S/N	Signal-to-noise Ratio
UV	Ultraviolet

In fluorescence microscopy, an optical microscope creates a magnified image of the fluorescence and phosphorescence of specimens excited by light. Autofluorescence is the intrinsic fluorescence of a specimen, which is often weak. To enhance fluorescence, tags are added, such as fluorescently labeled antibodies which precisely localize specific molecular components. Living cells and tissues may be labeled with a variety of parameter-indicating fluorophores to measure ion concentrations, electrical potentials and specific chemical species. Thick living specimens create problems of superimposition and haze from out-of-focus fluorescence, but advances in confocal fluorescence microscopy and multiphoton fluorescence microscopy now permit successful fluorescence imaging of thick living specimens with submicrometer three-dimensional resolution.

1 INTRODUCTION TO OPTICAL MICROSCOPY

1.1 Lateral Resolution

Optical microscopy provides useful magnification to about 2000 times. The diameter of the smallest object resolvable by an optical microscope, r, is given by the Abbe equation [Equation 1]:

$$r = \frac{0.6\lambda}{n \sin \alpha} \quad (1)$$

where λ is the wavelength of light, n is the refractive index of the object medium and α is the half-angle of light collection by the objective lens of the microscope. The quantity $n \sin \alpha$ is called the numerical aperture (*N.A.*) and characterizes the ability of objective lenses to resolve small objects. The *N.A.* of high-power oil immersion objective lenses can be as high as 1.4. As an example, for green light (0.54 μm), the resolution of an *N.A.* 1.4 objective lens is 0.23 μm.

1.2 Specimen Preparation for Brightfield Microscopy

For useful imaging near the limits of resolution, biological and nonbiological specimens must be prepared as thin films or slices, called sections. Sections of most materials of thickness less than 20 μm are translucent and nearly invisible. Even under the microscope, lack of contrast makes observation of microscopic structure almost impossible unless special optics are used, such as phase contrast microscopy and differential interference contrast (DIC) microscopy. Without such special optics, sections must be heavily stained by addition of strongly absorbing dyes. In medicine and biology, the dyes hematoxylin and eosin (H&E) are most commonly used to stain microscope sections. Hematoxylin is a basic (cationic) dye that binds electrostatically to acidic (anionic) sites of nucleic acids (DNA and RNA). Eosin is an acidic anionic dye that binds to proteins, which become cationic when the staining procedure is performed at pH 4–5. Under the microscope, structures rich in nucleic acids, such as cell nuclei, have the blue color of hematoxylin, whereas protein-rich regions of the cytoplasm display the red staining of eosin.

2 FLUORESCENCE OPTICAL MICROSCOPY

2.1 Fluorescence and Phosphorescence

Staining must be very intense to visualize specimens by brightfield microscopy. This limits sensitivity of brightfield microscopy to observe components of low abundance in a specimen. To improve sensitivity, specimens may be labeled with fluorescent tags. Absorbed light excites these tags to emit photons of longer wavelength. Fluorescence lifetime ranges between tenths of a nanosecond to about 100 ns and reflects the average time between absorbance of the excitation photon and release of the emitted photon. Quenching is any phenomenon that causes decay of the excited state without emission of a photon. Quenching commonly occurs when the energy of the excited state is transferred to solvent molecules and is dissipated as thermal energy. Light absorbance excites some molecules to a triplet state, which persists for hundreds of microseconds or longer before decaying to the ground state. For such molecules, release of a photon upon return to the ground state is called phosphorescence. Specialized fluorescence lifetime microscopes can image fluorescence and phosphorescence based both on lifetime and intensity. Thus, short- and long-lived emitters can be distinguished even if the wavelength of emission is identical.[1]

2.2 Epi-illumination

In fluorescence (and phosphorescence) microscopy, light of a specific wavelength illuminates the specimen to excite a specific absorbing species. Fluorescence emission is then magnified and imaged by the same basic optics as a conventional brightfield microscope. Special optical filters must be employed both to select the color of the excitation light and to distinguish fluoresced light from the excitation light. In a typical optical arrangement called epi-illumination, a dichroic mirror reflects the excitation light from a bright light source, such as a heated tungsten filament or mercury vapor lamp, into the microscope objective on to the specimen (Figure 1). Excitation light first passes through a barrier filter, which selects the desired wavelength of excitation. For example, a bandpass interference filter transmitting blue light between 470 and 500 nm might be employed to excite the green fluorescence of many fluorophores. Neutral density filters are also often needed to attenuate the excitation light to decrease photodamage and photobleaching. Fluorescence from excited fluorophores in the specimen passes back through the objective lens. Because dichroic mirrors can be constructed to reflect light of shorter wavelengths and transmit longer wavelength light, the dichroic mirror transmits only the fluoresced light, separating it from backscattered excitation light. After passing through another barrier filter, often a long-pass filter that transmits all light longer than a specified wavelength, the fluoresced light is formed into an image to be observed by the eye or recorded by photographic film or video camera. Epi-illumination fluorescence microscopes are very efficient at eliminating stray excitation light. As a result, fluorescence is imaged against a background of almost complete blackness. This accounts for the remarkable sensitivity of fluorescence microscopy to visualize fluorescently tagged specimens.

Figure 1 Scheme illustrating epi-illumination fluorescence microscopy. Light from a lamp passes through neutral density and interference barrier filters, reflects off a dichroic mirror and is projected on the specimen by the objective lens. Fluorescence excited by this illumination passes back through the objective lens, the dichroic mirror and an excitation barrier filter to be focused as an image on photographic film or video camera.

2.3 Confocal Fluorescence Microscopy

2.3.1 Problem of Imaging Fine Detail in Thick Specimens

Depth of field is the axial distance in the specimen space that is in focus in a single image. For conventional brightfield and fluorescence microscopes, the effective depth of field at high power is 2–3 μm. Since the lateral resolving power of optical microscopy is much greater than this depth of field, superimposition of detail within this field obscures structural detail that might otherwise be resolved. For specimens thicker than a few micrometers, light from out-of-focus planes is also superimposed, further degrading the image. In fluorescence microscopy, this out-of-focus fluorescence creates diffuse halos around in-focus objects under observation. In recent years, the technique of confocal microscopy has evolved to visualize fluorescence arising from only a very thin optical plane through the specimen.[2] Confocal images achieve submicrometer depths of field with virtually complete

rejection of light from out-of-focus planes. This smaller depth of field and rejection of out-of-focus light together produce images of remarkable detail and quality.

2.3.2 Pinhole Principle

The thin optical slices of confocal microscopy are obtained by illuminating one point at a time with a spot of light scanned across the specimen. The microscope objective focuses the illuminating beam, which is typically from a laser, to a tiny spot within the specimen (Figure 2). The diameter of these spots depends upon the wavelength of light and the *N.A.* of the objective lens (see Equation 1). Fluoresced light returns through the objective lens, and a dichroic mirror again separates the returning light from the illuminating light. After passing through an additional barrier filter, fluorescence is projected by the objective on to a small pinhole. Light originating from the in-focus cross-over point of the illuminating light beam is focused to a small spot precisely at the pinhole. This in-focus fluorescence passes through the pinhole to a light detector beyond, typically a photomultiplier. Fluorescence from above and below the focal plane is projected to spots behind and in front of the pinhole, respectively. As a result, out-of-focus fluorescence is spread out when it reaches the pinhole and does not traverse the pinhole aperture (Figure 2). In this way, the pinhole selectively transmits in-focus light and rejects out-of-focus light.

Figure 2 Scheme of a laser scanning confocal microscope. A laser beam passes through a barrier filter and is focused on a pinhole, which acts as a point source of light. A dichroic mirror reflects the laser beam into an $x-y$ scan generator and through to the objective lens. The scan generator together with the objective lens scans a diffraction-limited spot of light across the specimen. Fluoresced light passes back through the objective, scan generator, dichroic mirror and emission barrier filter to be focused on a pinhole aperture placed in the conjugate image plane. Light originating from the specimen plane of focus passes through the pinhole to a photomultiplier. Light from above and below the focal plane strikes the walls of the pinhole aperture and does not pass through to the photomultiplier. Photomultiplier output is fed to a computer.

To create a two-dimensional image, vibrating mirrors in the light path scan the illuminating light beam across the specimen.[3] The mirrors also ''descan'', returning fluorescence in order to focus it on the stationary pinhole. Computer memory then stores light detected by the photomultiplier, and a video monitor displays detected fluorescence in register with the movement of the light beam across the specimen.

2.3.3 Axial Resolution of Confocal Microscopy

The thickness of a confocal optical section decreases as the pinhole diameter decreases. The limit of resolution occurs when the pinhole becomes smaller than the diffraction limited spot (Airy disk) of in-focus light that is projected on it. Further decreases in pinhole diameter produce no further improvement of axial resolution (section thickness). Axial resolution (Z) at this limit is given by Equation (2):[4]

$$Z = \frac{2\lambda n}{(N.A.)^2} \tag{2}$$

Assuming green light (0.54 μm), oil immersion ($n = 1.55$) and an *N.A.* of the objective lens of 1.4, the axial resolution is 0.85 μm.

The better axial resolution of confocal microscopy improves the discrimination of individual small objects within a thick specimen, as compared with widefield microscopy. Confocal and nonconfocal images of cultured hepatocytes labeled with Rhodamine 123 illustrate the improvement (Figure 3a and b). Rhodamine 123 is a green-fluorescing cationic fluorophore that accumulates electrophoretically into the negatively charged mitochondria. In hepatocytes, mitochondria are round, oval and sometimes snake-like subcellular organelles of about 1 μm in diameter. When imaged by conventional epi-illumination fluorescence microscopy, individual mitochondria are easily identified at the cell periphery where the cytoplasm is the thinnest, but in thicker central regions superimposition of detail and out-of-focus fluorescence obscure the definition of the individual organelles (Figure 3a). Rather, an irregular mass of fluorescence occupies the cell center, suggesting falsely that the mitochondria are fused into a larger structure. By contrast, confocal microscopy shows that the mitochondria are well delineated individual structures, and the improvement of useful resolution is immediately obvious (Figure 3b).

Figure 3 Comparison of conventional and confocal fluorescence microscopy. (a) Conventional widefield fluorescence micrograph of rhodamine 123-labeled mitochondria in a cultured hepatocyte recorded by a low-light video camera. (b) Confocal fluorescence micrograph of another rhodamine 123-labeled hepatocyte. Magnification is approximately the same. (Adapted from Lemasters et al.[5])

2.3.4 Excitation Sources for Confocal Microscopy

In laser scanning confocal microscopy, the type of laser determines the wavelengths available to excite fluorescence: 488 and 514 nm for argon lasers, 543 nm for helium–neon lasers, 488, 568 and 647 nm for argon–krypton lasers and 351–365 nm for ultraviolet (UV)–argon lasers.[6] Some confocal microscope designs employ a white light source. With interference filters, virtually any excitation wavelength can then be selected, but the fluorescence images are generally dimmer than with laser illumination. The wavelength of excitation must be chosen to match the fluorescence excitation spectrum of the fluorophore under study, e.g. 488 nm for fluorescein and 543 or 568 nm for rhodamine. Similarly, dichroic mirrors and barrier filters must be appropriate for the emission spectrum. Sometimes a second dichroic filter is placed in the emission light path so that fluorescence of different wavelengths may be separated and detected. With multiline lasers or a combination of different lasers, specimens tagged with two or more fluorophores may be excited simultaneously. The different colors of fluorescence emission from these fluorophores can then be detected simultaneously using different photomultipliers. Simultaneous detection of multiple fluorophores is particularly advantageous for comparing dynamic changes of parameters of interest in living specimens.

2.4 Multiphoton Excitation Fluorescence Microscopy

2.4.1 Multiphoton Fluorescence Excitation

If two photons impinge on a fluorophore virtually at the same time, their energy can be absorbed simultaneously to produce fluorescence excitation. The energy yield from absorbance of two photons is equivalent to that of one photon of twice the energy (i.e. half the wavelength). Hence two photons of red light can excite a fluorophore that normally requires UV illumination. Importantly, the rate of two-photon excitation varies with the square of the light intensity, just as the rate of a chemical reaction, $A + A \longrightarrow B$, varies with the square of the concentration of A. Similarly, three-photon and higher order fluorescence excitation can be achieved, which varies with the cube and higher powers of intensity.

2.4.2 Multiphoton Fluorescence Imaging

The nonlinear dependence of multiphoton fluorescence excitation has a very important implication for laser scanning microscopy. As illustrated in Figure 4, the light intensity of a beam of laser light focused by the objective lens is greatest at the cross-over point. As light travels through this cross-over point, the beam spreads out again. Because two-photon excitation is dependent on the square of light intensity, the zone of fluorescence excitation is effectly confined only to the point of highest light flux, namely at the cross-over point. As the beam spreads out, fluorescence excitation drops off rapidly. Thus, as the laser beam is scanned across a specimen, fluorescence arises only from the plane traversed by the cross-over point of the laser beam. The result is a thin optical section, but without the necessity for detection through a pinhole.[7,8]

A further difference between multiphoton microscopy and pinhole confocal microscopy is that fluorescence need not be imaged through the optics of the microscope.

Figure 4 Scheme illustrating multiphoton excitation at cross-over of the focused laser beam.

Since the region excited by the two-photon phenomenon is intrinsically restricted to the plane of cross-over illumination, light may be collected directly by an external photomultiplier placed near the specimen. This detection configuration avoids light losses that occur when fluorescence is conducted back through the imaging system and scanner.

2.4.3 Laser Sources for Multiphoton Microscopy

To achieve efficient two- and three-photon fluorescence excitation, the instantaneous light intensity must be extremely high. Continuous illumination at such high power would almost instantly destroy specimens. Instead, pulsed lasers are employed to produce brilliant ultrashort 100–300-fs bursts of illumination. The instantaneous light intensity is sufficient to produce multiphoton excitation but the average power is much less because the individual pulses are separated by 10–13-ns intervals (75–100-MHz repetition rate). Currently, the most widely employed laser for multiphoton microscope systems is the pulsed Ti : sapphire laser, which is tunable between 680 and 1000 nm. When tuned to 700 nm, pulsed Ti : sapphire lasers produce two-photon excitation of UV-absorbing fluorophores. Longer wavelengths produce two-photon excitation of fluorescein- and rhodamine-like fluorophores. At 900 nm or greater, the Ti : sapphire laser can also achieve three-photon excitation of UV-absorbing fluorophores with simultaneous two-photon excitation of visible wavelength fluorophores. Modulation of the laser pulse width influences the relative strengths of two- and three-photon excitation. Shorter pulses favor three-photon excitation, whereas longer pulses produce relatively stronger two-photon excitation.[7]

2.4.4 Advantages of Multiphoton Microscopy Over Confocal Microscopy

Since photons are only absorbed by the target fluorophores at the cross-over point of the laser beam, essentially no photobleaching and photodamage occur above and below the image plane. Moreover, most biological tissue has little intrinsic absorbance of red and infrared (IR) light. Thus, at power levels required for both two- and three-photon excitation, collateral damage is virtually absent even after prolonged exposure. Because light scattering decreases with increasing wavelength and because intrinsic red- and IR-absorbing chromophores are in low abundance, biological tissues transmit red and especially near-IR light very well. Thus, the laser beam for multiphoton excitation penetrates deep into tissues. For both UV and visible wavelength fluorophores, fluorescence imaging deep into tissues by two- and three-photon microscopy becomes possible. This would be simply impossible by conventional one-photon fluorescence microscopy.

Unlike conventional fluorescence microscopy, the wavelength of emitted fluorescence in multiphoton microscopy is shorter than the excitation wavelength. Thus, emitted light scatters more than the excitation light. However, by using a photodetector placed near the specimen outside the microscope optics (nondescanned external detection) or by removing the pinhole from the detection light path, even scattered light can be captured with high efficiency. Such scattered light would not be collected by a conventional confocal microscope.

3 FLUORESCENCE LABELING

3.1 Autofluorescence

The most direct approach in fluorescence microscopy is observation of the intrinsic fluorescence or autofluorescence of specimens. In biology, oxidized flavoproteins, reduced forms of pyridine nucleotides [nicotinamide adenine dinucleotide (reduced form) (NADH) and nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH)] and α-tocopherol (vitamin E) are autofluorescent and can provide useful images. Autofluorescence can also be an undesirable artifact that obscures observation of specific fluorescent tags. Certain preparative techniques produce autofluorescence in biological specimens, particularly chemical cross-linking with glutaraldehyde and other fixatives.

3.2 Immunofluorescence

Much more commonly, specimens are labeled with specific fluorescent tags. In immunocytochemistry, a primary antibody is prepared against a specific cellular constituent, such as a protein or complex carbohydrate. In direct immunocytochemistry, this antibody is reacted with a fluorescent molecule, such as fluorescein or rhodamine isothiocyanate. After treatment of the specimen with the fluorescently labeled antibody, fluorescence microscopy then shows the cellular and subcellular distribution of the constituent of interest (Figure 5a). In indirect immunocytochemistry, the tissue section is first treated with unlabeled primary antibody, such as rabbit immunoglobulin G (IgG). Subsequently, the section is exposed to a fluorescently labeled secondary antibody against the primary antibody, such as goat anti-rabbit antibody (Figure 5b). In general, indirect immunocytochemistry produces brighter fluorescent labeling than direct immunocytochemistry, because several fluorescently tagged secondary antibodies bind to each primary antibody. Other high affinity binding reactions are also

Figure 5 (a) Direct and (b) indirect immunocytochemistry. In direct immunocytochemistry, a fluorescently labeled primary antibody binds directly to its target. In the indirect method, an unlabeled antibody binds the target. Subsequently, a fluorescently labeled secondary antibody binds the primary antibody.

useful to label biological specimens, such as the binding of fluorescently tagged phalloidin, a mushroom toxin derivative, to actin microfilaments.

3.3 Parameter-indicating Fluorophores in Living Cells and Tissues

Fluorescence microscopy is becoming an indispensible tool to study cells and tissues in their living state. Although autofluorescence sometimes provides useful signals, in general living specimens must first be labeled with one or more parameter-indicating fluorescent probes. These fluorophores constitute four broad categories: (1) probes of general cell function and integrity, such as cell viability, cell shape and volume, electrical potential, and membrane permeability; (2) markers of specific intracellular structures, such as mitochondria, lysosomes and endoplasmic reticulum; (3) probes of specific chemical species, such as ions, oxygen radicals, and thiols; and (4) fluorescent molecular markers of specific cellular proteins. Table 1 shows a partial list of parameter-indicating fluorophores useful in fluorescence microscopy of living cells.[9–36] A much more comprehensive listing can be found in Haugland.[20]

3.3.1 Probes of General Cell Function

3.3.1.1 Cell Viability and Integrity Cells are normally impermeable to large hydrophilic molecules unless a specific membrane transporter system exists. When cell viability is lost, this permeability barrier breaks down, which allows otherwise impermeant molecules to cross freely into and out of the cell interior.[9–11] For example, viable cells exclude the cationic fluorophore propidium iodide. When viability is lost, propidium iodide enters cells and binds to nuclear DNA. This binding enhances the red fluorescence of propidium iodide, which is readily visualized by fluorescence microscopy.

Other fluorophores, such as fluorescein and calcein, are retained by viable cells and are released only after loss of cell viability. These fluorophores are loaded into cells as their neutral, membrane-permeant ester derivatives. After the neutral esters have crossed into cells, endogenous esterases release the membrane-impermeant free acid form of the fluorophores, which becomes trapped in the cytoplasm. When cell viability is lost, the trapped dye is released. In theory, cells should retain these fluorophores indefinitely. However, many cells possess transporters that allow these anionic fluorophores to cross the plasma membrane and gradually leak from the cytoplasm. Thus, dye retention may not be as reliable as dye exclusion as an indicator of cell viability.

The fluorophore calcein labels the cytosol when cells are incubated with calcein AM ester at 37 °C. In some cell types, calcein uptake is almost exclusively in the cytosol and the nucleus. Mitochondria exclude calcein and appear by negative contrast as round dark voids in the fluorescence. These voids disappear after mitochondria injury causing increased mitochondrial membrane permeability and uncoupling of oxidative phosphorylation. In this way, redistribution of intracellular calcein can reveal increases of permeability of intracellular membranes.[12]

3.3.1.2 Cell Volume and Topography Cell shape, volume and surface topography are essential features

Table 1 Fluorophores for living cells and tissues

Cellular parameter	Fluorophore
General cell function	
Cell viability	Propidium iodide[9]
	Ethidium homodimer[10]
	Calcein AM ester[11]
Membrane permeability	Calcein[12]
	Fluorescein- and rhodamine–dextran[13,14]
Cell volume/topography	Calcein[15]
Membrane potentials	Rhodamine 123[16]
	TMRM[17]
	Tetramethylrhodamine ethyl ester[17]
	JC-1[18]
	Di-4-ANEPPS[19]
Subcellular compartments	
Mitochondria	Rhodamine 123[16]
	TMRM[17]
	Tetramethylrhodamine ethyl ester[16]
	JC-1[18]
	MitoTracker Green® and MitoTracker Red®[20]
Endosomes	Rhodamine microspheres[21]
Lysosomes	LysoTracker Red®[20]
	Fluorescein- and rhodamine–dextran[21]
Golgi	BODIPY-ceramides[20,22]
Endoplasmic reticulum	$DiOC_6(3)$[23]
	ER-Tracker Blue-White DPX®[20]
Specific chemical species	
Ca^{2+}	Fura-2[24]
	Indo-1[24]
	Fluo-3[25]
	Fluo-4[20]
	Rhod-2[25]
pH	BCECF[26]
	SNARF-1[15,20]
Mg^{2+}	Mag-Fura[27]
Na^+	SBFI[28]
K^+	PBFI[28]
Glutathione	Monochlorobimane[29,30]
Protein thiols	Monobromobimane[29,30]
Oxygen radicals	Dichlorofluorescein[31]
	Dihydrorhodamine 123[32]
	Dihydroethidium[33]
Molecular tags and indicators	
Green fluorescent proteins	GFP[34]
	BFP
	CFP
	YFP
Bioengineered Ca^{2+} indicators	Cameleons[35,36]

AM, acetoxymethyl; TMRM, tetramethylrhodamine methyl ester; JC-1, tetrachlorotetraethylbenzimidazolylcarbocyanine; Di-4-ANEPPS, 4-dibutylaminonaphthalenylethenylsulfopropyl pyridium; BODIPY, boron dipyrromethene; $DiOC_6(3)$, dihexyloxacarbocyanine; BCECF, 2′,7′-biscarboxyethylcarboxyfluorescein; SNARF, seminaphthorhodafluor; BFP, blue fluorescent protein; CFP, cyan fluorescent protein; GFP, green fluorescent protein; SBFI, sodium-binding benzofuran isophthalate; PBFI, potassium-binding benzofuran isophthalate; YFP, yellow fluorescent protein.

(b) Scanning electron micrograph of another cardiac myocyte at about the same magnification. (Adapted from Chacon et al.[15])

of cell structure. By labeling the intracellular space of cells with a fluorophore such as calcein, serial confocal images through the entire thickness of individual cells can be used to reconstruct cell volume and shape. Such reconstructions, or volume renderings, employ contour-dependent shading to depict cellular shape and surface detail, as illustrated in Figure 6(a) for a single cardiac myocyte in culture. Such volume renderings rival scanning electron micrographs in the depiction of topographical detail, although electron microscopy achieves superior lateral spatial resolution (Figure 6b). However, confocal fluorescence microscopy permits the repeated imaging of living cells, unlike scanning electron microscopy, which requires that specimens be chemically fixed, dried and coated with metal. Repeated volume renderings also quantify changes of cell volume over time.[15]

3.3.1.3 Electrical Potential Both the plasma membrane and mitochondria maintain a negative transmembrane electrical potential ($\Delta\Psi$). As a consequence, lipophilic cationic fluorophores such as rhodamine 123 and TMRM accumulate electrophoretically in response to these membrane potentials.[16,17] Uptake is related to $\Delta\Psi$ by the Nernst equation [Equation 3]:

$$\Delta\Psi = -60 \log \frac{F_{\text{in}}}{F_{\text{out}}} \tag{3}$$

where F_{in} and F_{out} represent the concentrations of the monocationic fluorophore inside and outside the membrane, respectively. From Equation (3), uptake ratios of 10, 100 and 1000 : 1 signify $\Delta\Psi$ values of -60, -120 and -180 mV, respectively. $\Delta\Psi$ of the plasma membrane ordinarily ranges between -30 and -90 mV, depending on cell type, and mitochondrial $\Delta\Psi$ is -100 to -190 mV. These $\Delta\Psi$ values are additive, such that mitochondria are as much as 240 mV more negative than the extracellular space, corresponding to a fluorophore concentration ratio of 10 000 : 1 inside mitochondria relative to the outside of the cell.

From confocal and multiphoton fluorescence images, average extracellular fluorescence intensity of a potential-indicating fluorophore can be divided into intracellular fluorescence for each picture element or pixel.[15] By applying the Nernst equation to each pixel, electrical potential of every point inside the cell relative to the extracellular space can be calculated and displayed as a pseudocolor map. Differences in electrical potential across membranes then represent the corresponding transmembrane potentials.

Figure 7 illustrates the intracellular electrical potential measured in a cultured rat hepatocyte. Under the cell surface and in the nucleus, the electrical potential is about -40 mV. Since extracellular electrical potential represents the ground (0 mV), $\Delta\Psi$ is -40 mV across the plasma membrane. Distributed throughout the cytoplasm are also more electronegative mitochondria with potentials as great as -160 mV. Since the electrical potential of the surrounding cytosol is -40 mV, the difference, -120 mV, represents mitochondrial $\Delta\Psi$. Mitochondria appear to show heterogeneity of electrical potential. This heterogeneity is due, at least in part, to the fact that not

Figure 7 Distribution of electrical potential in a hepatocyte. Red fluorescence of a TMRM-loaded hepatocyte was imaged by laser scanning confocal microscopy. The distribution of intracellular electrical potential was determined by the application of Equation (3) to each pixel in the image. (From E. Chacon, G. Zahrebelski, J.M. Reece, A.-L. Nieminen and J.J. Lemasters, unpublished work.)

all mitochondria extend completely through the confocal slice, causing electrical potential to be underestimated.

3.3.2 *Markers of Specific Intracellular Structures*

Many fluorophores tag specific intracellular structures. As discussed above, cationic fluorophores such as rhodamine 123 and TMRM brightly label mitochondria (Figures 3 and 7). Carbocyanine dyes label endoplasmic reticulum[23] and fluorescent ceramide conjugates label the Golgi apparatus.[20–22] Weak bases, such as LysoTracker Red®,[20] accumulate into acidic lysosomal compartments (Table 1).

3.3.3 *Probes of Specific Chemical Species*

3.3.3.1 Ion Indicators and Ratio Imaging Many fluorophores measure ion concentration in individual living cells. Typically, these fluorophores are loaded as their neutral ester derivatives, as described above for calcein. Inside cells, the fluorescence of ion-indicating fluorophores depends on both the ion concentration and the amount of fluorophore present in the light path. When ion binding to a fluorophore causes a red or blue shift of the excitation or emission spectrum, a ratioing procedure may be used to correct for changes in fluorophore concentration (Figure 8).[37] Images are acquired at two different excitation or emission wavelengths: one wavelength that changes with changing ion concentration, and another wavelength that either does not change or changes in the opposite direction. After background subtraction to remove any contribution of nonspecific scattered light

Figure 8 Principle of ratio imaging. See text for details.

and instrumental dark current, the fluorescence image at the first wavelength is divided by the image at the second wavelength on a pixel-by-pixel basis. The result is a ratio image. For example, with 568-nm excitation, the fluorescence of carboxy SNARF-1 emitted at 640 nm increases as the pH increases, but emission at 585 nm does not change. Consequently, the ratio of fluorescence at the two wavelengths is a function of pH but is independent of SNARF-1 concentration.[15] Ratioing eliminates variations in image brightness due to differences of regional fluorophore concentration, dye leakage over time and photobleaching. Using a calibration curve, ratio images are converted to maps of intracellular ion distribution. Not all ion-indicating fluorophores are suitable for this ratioing procedure. Only indicators that have ion-induced spectral shifts, such as Indo-1 and Fura-2 for Ca^{2+}, SNARF-1 and BCECF for pH, SBFI for Na^+, PBFI for K^+ and Mag-Fura for Mg^{2+} (Table 1). Unfortunately, all these dyes except SNARF-1 and BCECF require UV excitation.

Ion Indicators and Nonratiometric Indicators Green-fluorescing Fluo-3 and Fluo-4 and red-fluorescing Rhod-2 are useful visible wavelength indicators of free Ca^{2+} (Table 1). Their binding affinity for Ca^{2+} is in the range 400–500 nM and their fluorescence increases 30–80-fold after Ca^{2+} binding. However, Ca^{2+} binding does not produce a spectral shift. Hence ratio imaging cannot be applied. Nonetheless, Fluo-3, Fluo-4 and Rhod-2 are useful to measure relative changes of free Ca^{2+}, especially

in confocal and multiphoton microscopy which produce uniform optical slices through cells of interest.

Compartmental Loading of Ion Indicators Cation-indicating fluorophores are hydrophilic multivalent carboxylic acids that do not cross cellular membranes. To load these indicators, cells are incubated with their uncharged acetate or AM ester. The esters cross the plasma membrane, become de-esterified and are thus trapped in the cytoplasm. Since esterases reside in several different cellular compartments, ion-indicating fluorophores can distribute into several different compartments after ester loading, often in a heterogeneous fashion.

In many cell types, the temperature of ester loading strongly influences the intracellular distribution of various fluorophores.[12] Warm ester loading at 37 °C favors cytosolic uptake, whereas cold ester loading at 4 °C promotes fluorophore entry into both the cytosol and membranous organelles, in particular the mitochondria. Apparently during warm loading, cytosolic esterases hydrolyze the fluorophore esters before they have the chance to diffuse into mitochondria. By contrast, cold temperature slows esterase activity such that esterified probes are able to diffuse across the cytosol and into mitochondria before hydrolysis occurs. The temperature dependence of ester loading varies with cell type and also with the particular fluorophore used. In cardiac myocytes, for example, calcein and Fluo-3, a green-fluorescing Ca^{2+} fluorophore, localize to the cytosol after warm ester loading, whereas Indo-1, a blue-fluorescing Ca^{2+} indicator, and SNARF 1 load into mitochondria even at 37 °C.[12,38]

Anionic fluorophores in the cytosol gradually leak across the plasma membrane through an organic anion carrier,[39] but release of fluorophores localized to mitochondria and other organelles is much slower. Selective release from the cytosol can be used to achieve selective mitochondrial loading of ion-indicating fluorophores. First, cold loading is used to distribute a fluorophore into both the cytosol and the mitochondria. Subsequently, the loaded cells are incubated at 37 °C for several hours. During the warm incubation, fluorophore in the cytosol leaks across the plasma membrane and is lost to the extracellular medium, but fluorophore in the mitochondria and other organelles (chiefly lysosomes) remains. Subsequently, warm ester loading can be used to load a second fluorophore into the cytosol. In this way, one fluorophore enters the cytosol and another fluorophore enters mitochondria and organelles (Figure 9a and b). By using two-color fluorescence microscopy, the fluorescence of the two fluorophores can be independently measured to compare, for example, changes of cytosolic and mitochondrial Ca^{2+} directly.[40–42]

Figure 9 Simultaneous loading of fluorophores into different subcellular compartments. The Ca^{2+} indicator Rhod-2 was localized to the mitochondria of a cardiac myocyte by a cold loading–warm incubation protocol. Subsequently, Fluo-2, another Ca^{2+} indicator, was loaded into the cytosol by warm ester loading, them low Na^{+} buffer was added to increase intracellular Ca^{2+} and saturate the Ca^{2+}-dependent fluorescence of both indicators. Rhod 2 fluorescence (a) was present in mitochondria, but not in toxic blebs (double arrows), whereas Fluo 3 fluorescence (b) was diffusely present in both the cytosol and the blebs. (Adapted from Trollinger et al.[40])

3.3.3.2 Reactive Oxygen Species and Cellular Thiols Incomplete reduction of oxygen causes formation of reactive oxygen species (ROS), including superoxide, hydrogen peroxide and hydroxyl radical. ROS are formed during normal metabolism and as a consequence of various pathological processes. Certain nonfluorescent compounds, such as dichlorofluorescin, dihydrorhodamine 123 and hydroethidium, react with ROS to form highly fluorescent derivatives (Table 1).[31–33] Fluorescence microscopy can then be used to image the rate and subcellular location of ROS formation in single cells.[31] Glutathione and protein thiols are important targets of oxidation by ROS. Monochlorobimane reacts with glutathione and monobromobimane reacts with both glutathione and protein thiols to form fluorescent adducts. These adducts may also be imaged by fluorescence microscopy to quantify the intracellular distribution of protein and nonprotein thiols in single cells.[29,30]

The oxidation–reduction status of pyridine nucleotides [nicotinamide adenine dinucleotide (oxidized form) (NAD^{+}) and nicotinamide adenine dinucleotide phosphate (oxidized form) ($NADP^{+}$)] can be conveniently monitored by imaging of autofluorescence. NADH and NADPH, the reduced forms of NAD^{+} and $NADP^{+}$, are

excited to emit blue light (450 nm) by near-UV light (340 nm). NADH and NADPH fluorescence is highly quenched in the cytosol. Consequently, nearly all NADH and NADPH fluorescence arises from mitochondria.[31] The green fluorescence of oxidized flavin can also be used to monitor the oxidation–reduction of flavoproteins in mitochondria and elsewhere.[43]

3.3.4 Molecular Markers

Recently, the GFP of the jelly fish *Aequorea victoria* has emerged as an important fluorescent reporter of gene expression and protein localization in living cells.[34] GFP is a 27 000-Da monomer consisting of 238 amino acids in an 11-stranded β-barrel surrounding a coaxial α-helix containing the chromophore. Wild-type GFP absorbs near-UV and blue light and emits green light with a maximum at 509 nm. Several red- and blue-shifted GFP mutants have been developed to increase brightness and yield emissions of blue, cyan and yellow in addition to green.

To use GFP, fusion constructs are made of the cDNA for GFP and a cDNA of a target protein. After gene transfer by transfection or other means (e.g. viral vectors), living cells use this DNA to synthesize a fusion protein comprised of the target protein and its GFP tag. Using fluorescence microscopy, the subcellular localization and intracellular trafficking of the GFP fusion protein can then be followed in the living state (Figure 10a and b). Fluorescence resonance energy transfer occurs between the different-colored GFP mutants and is the basis for the development of unique new chimeric indicators. For example, Ca^{2+}-indicating fluorophores have been developed by fusing cyan-emitting fluorescent protein (CFP) with calmodulin and yellow-emitting fluorescent protein (YFP). Ca^{2+} binding then alters fluorescence energy transfer between CFP and YFP. These proteins are called cameleons and can be imaged by fluorescence microscopy.[35,36] Mutagenesis and molecular engineering of GFP should continue to provide useful new molecular probes for fluorescence microscopy.

Figure 10 Confocal fluorescence microscopy of cytochrome *c* GFP. Pheochromocytoma cells were transfected with cytochrome *c*-GFP and co-loaded with MitoTracker Red®. The green fluorescence of cytochrome *c*-GFP (a) co-localizes with the red fluorescence of MitoTracker Red® (b). The punctate structures in both images are individual mitochondria. 4 CONCLUSIONS

Fluorescence microscopy is a powerful tool to identify and localize specific molecular components with lateral resolution of 0.2 μm. New techniques of confocal and multiphoton microscopy also permit an axial resolution approaching 0.8 μm even in thick specimens. Unlike electron microscopy, fluorescence optical microscopy allows nondestructive observation of living cells and tissues. The number of specific parameter-indicating fluorophores useful for live-cell imaging continues to increase. These include markers of cell shape and volume, organelles, membrane potentials, ions and other chemical constitutents. With the advent of GFP and its many mutants, virtually any cellular protein can be fluorescently tagged in the living state. These developments make fluorescence microscopy an indispensible tool for the molecular biologist, cell biologist, physiologist and others, both inside and outside the life sciences.

ABBREVIATIONS AND ACRONYMS

AM	Acetoxymethyl
BCECF	2′,7′-Biscarboxyethylcarboxy-fluorescein
BFP	Blue Fluorescent Protein
BODIPY	Boron Dipyrromethene

CFP	Cyan Fluorescent Protein
Di-4-ANEPPS	4-Dibutylaminonaphthalenyl-ethenylsulfopropyl Pyridium
DIC	Differential Interference Contrast
$DiOC_6(3)$	Dihexyloxacarbocyanine
GFP	Green Fluorescent Protein
H&E	Hematoxylin and Eosin
IgG	Immunoglobulin G
IR	Infrared
JC-1	Tetrachlorotetraethylbenzimida-zolylcarbocyanine
NAD^+	Nicotinamide Adenine Dinucleotide (Oxidized Form)
NADH	Nicotinamide Adenine Dinucleotide (Reduced Form)
$NADP^+$	Nicotinamide Adenine Dinucleotide Phosphate (Oxidized Form)
NADPH	Nicotinamide Adenine Dinucleotide Phosphate (Reduced Form)
PBFI	Potassium-binding Benzofuran Isophthalate
ROS	Reactive Oxygen Species
SBFI	Sodium-binding Benzofuran Isophthalate
SNARF	Seminaphthorhodafluor
TMRM	Tetramethylrhodamine Methyl Ester
UV	Ultraviolet
YFP	Yellow Fluorescent Protein

This article provides an overview of the general properties of organized assembly (ordered media) systems, such as aqueous surfactant and bile salt micelles, lipid (liposomes) and surfactant vesicles, and cyclodextrins (CDs), and summarizes their utilization to enhance the performance of analytical fluorescence measurements. In many instances, organic molecules and metal complex species when included within a CD cavity or solubilized and bound to surfactant aggregates exhibit enhanced fluorescence, improving detectability of such analytes. The altered microenvironment within the organized medium can impede the interfering action of other species (inorganic or organic) present in the sample matrix, which often improves the selectivity of the analytical method. These benefits of improved sensitivity and selectivity arise from the compartmentalization, isolation, and shielding of the excited singlet state of the guest analyte from quenching and nonradiative decay processes, as well as preventing side reactions that otherwise can occur in bulk solution (or sample matrix). Organic solvents or time-consuming extraction steps can also be avoided, owing to the increased solubility of nonpolar organic or inorganic reagents and/or analyte molecules in water in the presence of the organized medium, allowing the use of an aqueous medium to perform the procedure. The possibility of conducting reactions and forming fluorescent organic or metal chelates in micellar (or other organized) media that are not observed in a bulk homogeneous solvent system serves to expand the scope of possible chemistries for design/development of new, unique, and improved fluorescent assays. Examples of fluorescent methods for determination of both organic and inorganic analytes are provided, which serve to illustrate the advantages and benefits accrued from the use of the micelles, vesicles, liposomes, or CDs in such procedures, along with experimental considerations and cautions in utilizing organized media.

1 INTRODUCTION

The past 35 years has witnessed ever-increasing interest in and utilization of the effects of organized assemblies (also termed *ordered media*) on photophysical and photochemical processes and reactions.[1–8] Reactants accommodated in such assemblies, i.e. normal and reversed micelles, vesicles and liposomes, CDs, etc., often achieve a greater degree of organization and altered microenvironment compared to that in bulk homogeneous solution, which may promote unique general properties and reaction features, characteristics which may mimic processes in biosystems and have wide applications in chemical analysis and separation science.[9–16]

This article focuses on several types of aqueous-based organized assembly (also referred to as *ordered media* or *membrane mimetic*) systems and their utilization to enhance analytical luminescence measurements. Included for discussion are the aqueous (normal) surfactant and bile salt micelle, aqueous synthetic surfactant vesicle and liposome, and aqueous CD systems. Following a brief description of these different organized assemblies and their basic properties, examples of applications involving such media in the area of analytical fluorescence methodology are surveyed. The goal is to present a general overview of the different possible beneficial roles and uses of such media in analytical luminescence spectroscopic measurements. The overview is intended to be more applied and illustrative in nature rather than being a comprehensive discussion of all the voluminous reported work in this area. For more fundamental information and details on the fluorescence technique in general, the reader is referred to a monograph on this topic[17]

(*see* **Pervaporation, Analytical**; **Electronic Absorption and Luminescence: Introduction**).

2 BRIEF DESCRIPTION OF ORGANIZED ASSEMBLIES

Of the many different organized assemblies and supramolecular systems reported in the literature, this article restricts itself to those surfactant aggregate systems and CD hosts that exist in aqueous solution. This choice was dictated by the fact that most of the reported applications in analytical fluorescence measurements have utilized such media. Detailed discussion of all aspects and salient features of the chemistry and properties of such surfactant and CD ordered media is beyond the scope of this article. More fundamental information on these systems can be obtained by consulting the cited monographs, reviews, and research articles on desired topics mentioned herein.

2.1 Survey of Surfactant Aggregate Systems

Surfactant (detergent) molecules, which contain an alkyl hydrophobic chain (tail) and a polar head group, are capable of forming aggregate supramolecular assemblies that exhibit properties distinctly different from those of the individual monomers prior to aggregation. Depending on the lipophilic–hydrophilic balance, a variety of aggregate morphologies, such as normal micelles, rods, disks, planar bilayers, vesicles, liposomes, and hexagonal phases, among others, have all been observed. With increasing surfactant concentration, morphologies ranging from micelles (L_1), through a cubic array of micelles (I_1), hexagonally packed rods (H_1), cubic bicontinuous spheres (V_1), to lamellae (L_3) where phase inversion takes place, and inverted morphologies develop.[11,12,18,19] Among these, this overview focuses on just the normal aqueous surfactant and bile salt micelle, liposome, and synthetic vesicle systems. A monograph addresses the use of reverse micelles in chemical analysis, including their utilization in fluorescence measurements.[19]

2.1.1 Normal Surfactant Micelles

In terms of actual analytical applications, aqueous (or normal) surfactant micelle systems have probably been the most frequently employed form of surfactant-based organized media in chemical analysis applications. Normal micelles are formed in aqueous solution by the aggregation of amphiphilic surfactant molecules. In simplest terms, the micellar entity is considered to be a globular structure in which the alkyl hydrocarbon core region is surrounded by a hydrophilic outer region comprising the surfactant head group (which can be cationic, anionic, zwitterionic, or nonionic), counterions, and water molecules (Figure 1).[2,11,12,18,20,21] The minimum surfactant concentration required for micelle aggregate formation is referred to as the *critical micelle concentration* (CMC). At concentrations below this value in solution, the surfactant molecules exist as solvated monomers. The number of individual surfactant molecules present in a micelle aggregate is referred to as the *aggregation number* (N).[11,12,18] Typically, such aggregates contain 60–150 surfactant molecules. It should be stressed that the micellar species is not a permanent (bonded) entity, but a dynamic structure that exists in equilibrium with its monomers, with the monomeric

Figure 1 Artistic representation of an idealized cross section of an aqueous normal micelle. The polar headgroups (◯) and hydrophobic tails (–) are schematically indicated to show only their relative locations but not their actual numbers, distributions, or configurations (the counterions, which would be associated with an ionic micelle, are not shown). The dotted line encompasses most of the hydrophobic core region of the micelle. Analytes can bind to the micellar aggregate at different locations. For example, a charged analyte (A) would be electrostatically repelled from the micelle surface if it were of the same charge type as the ionic micelle. An oppositely charged analyte ion (B) would be electrostatically attracted to the micellar surface and ion exchange with the micelle counterion. A neutral hydrophobic analyte molecule (C) would partition towards the nonpolar core region of the micelle depending upon its specific hydrophobicity. A neutral amphiphilic solute (D) might attempt to align itself with the surfactant molecule so as to maximize the electrostatic, hydrogen-bonding, and/or hydrophobic interactions possible between itself and the micelle surfactant molecules. (Adapted with permission from Hinze et al.[20])

surfactant molecules both entering and exiting the micelle.[11,12,18,21,22]

The CMC values for surfactant micelles have been determined from breaks in plots of the luminescence intensity of an organic probe molecule as a function of surfactant concentration as a consequence of alteration of the microenvironment experienced by the probe upon formation of and binding to the micelle aggregate.[22–92] Table 1 includes the CMC values for some classic micelle-forming surfactants. CMC values can be altered owing to the presence of the analyte and any other components required to adjust the pH and/or ionic strength.[93–99] For instance, the CMC of sodium dodecyl sulfate (SDS) in water was determined as 0.1 g per 100 mL, whereas a value of 0.2 g per 100 mL was observed in the presence of 120 ppm of the analyte, fenproporex.[96] The CMC of SDS was likewise altered from 8.1 mM in water to 1.1 mM in the presence of 0.125 M NaCl;[22] whereas the CMC of cetyltrimethylammonium chloride (CTAC) (hexadecyltrimethylammonium chloride) was 1.3 mM in water, it was only 0.28 mM in an aqueous 0.010 M NaOH solution. For cetyltrimethylammonium bromide (CTAB) (hexadecyltrimethylammonium bromide), the CMC in water is 0.92 mM, whereas it is 0.31 mM in the presence of 1.0 M sulfuric acid.[100] The CMC of SDS increased from 8.1 to 15.0 mM in the presence of 6.0 M urea whereas that of Triton X-100 changed from 0.20 to 0.60 mM in the presence of 3.0 M urea.[73] In

Table 1 Summary of some pertinent properties of bulk solvent and organized assembly systems, including CMC values for micelle-forming surfactants/bile salts

	Medium	CMC (mM)	ε[a]	$E_T(30)$[b]	η (cP)[c]	Py^*[d]
Bulk solvents	Bulk water (H_2O)	–	78.54	63.1	0.89	1.79

[a] Dielectric constant (ε) for the micelle–water interface; data taken from the literature.[32–34,40,41,43,45,50,52,53,56,58,61,62,64,68,71,75,77,90]
[b] Refers to Dimroth and Reichardt's empirical solvent polarity scale; data taken from the literature. [23,28,29,37,48,52,66,67,69,71,89]
[c] Refers to the microscopic viscosity at 20–25 °C; data taken from the literature.[23,26,31,39,42,44,50–52,57,64,72,75,78,79,81–85,87,89] The microviscosity is temperature dependent; for instance, for SDS η varies from 6 cP at 30 °C to 13 cP at 10 °C and 17 cP at 0 °C; similarly, the values for CTAC are 18, 49, and 70 cP, respectively, for the same temperatures.[79]
[d] Refers to the Dong–Winnik Py^* solvent polarity scale based on the photophysical properties of pyrene. Values taken from the literature.[47,54,55,57,76,77,80,86]
[e] Refers to zwitterionic *N*-dodecyl-*N,N*-dimethyl-3-ammonio-1-propanesulfonate.
[f] Refers to γ-palmitoyl L-α-lysolecithin.
[g] Temperature was 50 °C.
[h] Value depends upon the temperature, with η decreasing with an increase in temperature, vesicle charge, nature and binding site of probe molecule, and whether small (sonicated) unilamellar vesicles (SUVs) or multilamellar vesicles (MLVs) are present.
[i] Refers to egg PC or egg lecithin.
[j] Depends upon the actual CD concentration; $\varepsilon = 72$ at [β-CD] = 1 mM and 41 at [β-CD] = 10 mM.
NaL, sodium laurate; SDS, sodium dodecyl sulfate; TDAB, tetradecyltrimethylammonium bromide; DTAC, dodecyltrimethylammonium chloride; NaC, sodium cholate; NaDC, sodium deoxycholate; NaTC, sodium taurocholate; DPPC, dipalmitoylphosphatidylcholine; DMPC, dimyristoylphosphatidylcholine; PC, phosphatidylcholine; DHP, dihexadecyl phosphate; DODAB, dioctadecyldimethylammonium bromide.

some cases, the presence of another hydrophobic species, particularly dye molecules, can induce micellization of surfactants.[101] Such aggregated species are sometimes referred to as *dye-rich induced micelles*.[102] Addition of CDs can also induce aggregation of ionic surfactants at concentrations below their normal CMC.[103] The CMC and aggregation number of aqueous normal micelles were found to be almost independent of pressure.[81] Typically, there is a slight increase in the CMC of ionic surfactants with increased temperature above ca. 30 °C.[94,97,104,105] For instance, the CMCs for CTAB, CTAC, and SDS, which are 0.92, 1.3, and 8.1 mM, respectively, at 25 °C, increased to 1.5, 2.0, and 10.4 mM, respectively, at 65 °C.[94,97,104] The addition of organic solvents to aqueous solutions can preclude the formation of surfactant micellar aggregates.

Typically, the presence of 20–40% (v/v) of organic cosolvents (such as methanol, ethanol, and acetonitrile) in water precludes micelle formation. In fact, this has been observed using fluorescent compounds, i.e. drastic reductions in fluorescence intensity (FI) in this range of added cosolvent.[106–113] Dilution of micelle-containing solutions with water can also result in destruction of the micelles if the final surfactant concentration is below the CMC for that surfactant.

A number of monographs provide a more complete description of surfactant and micellar systems and their properties and salient features.[6,11,12,18,21,94,114–116]

2.1.2 *Bile Salt Surfactant Aggregate Systems*

In comparison with the classical linear aliphatic surfactants, the bile salts have a different molecular structure and stereochemistry. The bile salts are rigid, facial amphiphilic molecules and do not contain the usual polar head group and apolar tail of the classic micelle-forming surfactants. Instead, they possess a steroidal ring structure and are crescent shaped, with the hydrophobic convex side containing the hydrocarbon elements of the steroid ring along with the angular methyl groups, while the more polar concave side bears the hydroxy substituents.[117,118] When bile salts are dissolved in water, they also form aggregate species termed micelles above the CMC, as do classical linear anionic surfactants. However, their aggregation behavior is more complex, showing more gradual (and successive) changes in aggregate size with concentration. Bile salt aggregates in aqueous solution consist of transient species (i.e. monomers, dimers, tetramers, ..., higher oligomers) in dynamic equilibrium with one another. The relative population of these structures is very sensitive to the conditions of the solution, being influenced by the concentration of the bile salt, the absence or presence of additives in the system, and the temperature.[118,119] Table 1 also provides the CMC values for some bile salt surfactant micelle systems.

Bile salt aggregation is viewed as stepwise formation of globular primary bile salt micelles consisting of 2–10 monomers held together by hydrophobic interactions between the nonpolar backs of the bile salt molecules which constitute the interior region with the more polar hydroxyl and carboxylate groups projecting outward and accessible to water molecules according to the Small model. In the next stage, at high bile salt concentrations (and/or added salt), larger secondary bile salt aggregates are formed by mutual association of the primary micelles as a consequence of intermolecular hydrogen bonding between the primary micelle's bile salt hydroxyl and side-chain groups.[117] In addition to this model, a helical model for bile salt aggregates has also been proposed.[119]

In general, it is thought that bile salt aggregate systems are more hydrophilic than conventional SDS micelles.[120] The bile salt micelle systems are less surface active than conventional aqueous normal micelles.[119] As a consequence, bile salt micelle solutions do not form suds/foam as much; this is very useful in the preparation and manipulation of such solutions, especially if gas purging is required as in some fluorescence measurements.[121] The micellar properties of bile salts, such as sodium taurocholate (NaTC), are relatively insensitive to experimental conditions.[122] Thus, compared with the normal aqueous micellar systems, the bile salt media are also much more versatile and flexible in terms of their tolerances of pH, ionic strength, temperature, and counterion concentrations and are less likely to precipitate.[121,123] Bile salt solutions can tolerate the presence of greater concentrations of additives, such as organic solvents, compared with conventional micelles such as SDS, without disruption of their aggregate structure.[119,124] They are therefore more robust aggregate systems than traditional aqueous normal micelles.[122] In addition, bile salts and their micellar aggregates are chiral entities, so they can function as a chiral selector and differentially bind the enantiomers of some organic compounds.

A monograph provides additional information on bile salt/acid systems and their utilization in chemical analysis applications.[125]

2.1.3 *Liposome/Synthetic Vesicle Systems*

Amphiphiles with long alkyl double chains such as the phospholipids or some synthetic amphiphiles form aqueous compartments enclosed by a lipid–surfactant bilayer, known as *vesicle* or *liposome* aggregate systems, when dispersed in aqueous solution. The hydrocarbon tails of the lipid or surfactant molecules are sequestered inside the bilayer, and the polar head groups stick out into the aqueous phase – inside and outside the compartment.[126] A macroscopically isotropic small unilamellar vesicle (SUV) can be formed via ultrasound sonication of a lipid or surfactant solution above its phase transition temperature.[127,128] Alternatively, SUVs can be prepared by injecting/infusing a small aliquot of an ethanolic solution of the lipid through a thin needle into a rapidly stirred buffer solution at a temperature 15 °C higher then the transition temperature of the phosphatidylcholine (PC) lipid employed.[129,130] The lamellar phase transition temperature (T_M) of dimyristoylphosphatidylcholine (DMPC),

dipalmitoylphosphatidylcholine (DPPC) and dimyristoylphosphatidylserine (DMPS) are 20–24, 34–42, and 31–39 °C, respectively.[71,129–134] The latter recipe produces SUVs having an average diameter of 25–50 nm.[129] A large unilamellar vesicle (LUV) can also be prepared from such a lipid by variation of the preparation conditions to yield vesicles (liposomes) with a radius in the range 0.05–5 μm.[18,130,135–137] Such monolamellar vesicles can also be prepared by the so-called detergent method.[138–140] Several reports provide recipes for the different methods of vesicle/liposome preparation, the type(s) of liposomes formed by each, and their advantages/disadvantages.[18,140–144]

In addition to the multilamellar vesicle (MLV) (multicompartment, onionlike structure) type, whose diameters are in the range 1000–8000 Å, the unilamellar systems can also be prepared from lipids such as egg PC, bovine phosphatidylserine (PS), and egg phosphatidylglycerol (PG).[18,132,145] Some synthetic surfactants can also produce bilayer aggregates.[18] In particular, double-chain ammonium amphiphiles such as didodecyldimethylammonium bromide (DDAB), dihexadecyl phosphate (DHP), and dioctadecyldimethylammonium chloride (DODAC) or dioctadecyldimethylammonium bromide (DODAB) also belong to a representative class of such bilayer-forming compounds.[146–150] The phase transition temperature for DODAC vesicles is 37 °C. For vesicle systems formed by dispersing lipid or synthetic surfactant molecules in aqueous medium, there are two types of water molecules present in the system – those in the bulk and those enclosed within the water pool of the vesicle (liposome).[131] In general, the water pool of vesicles is much larger in comparison with that in reverse micelles. Vesicles/liposomes are dynamic aggregate systems since they can exhibit phase transition and fusion behavior and are osmotically active.[18] For most analytical applications, the single-compartment bilayer liposomes (or vesicles) formed by the sonication method are probably ''best'' since they possess a more uniform size distribution and can be more reproducibly prepared. Purification of liposomes from the free monomeric lipid, detergent, and unencapsulated solutes can be accomplished either by gel filtration chromatography or dialysis.[137,141]

Although there are many similarities in properties between surfactant vesicles/liposomes and micelles, there are some important and notable differences.[18,137,151] Structurally, the interior volume of vesicle/liposome aggregates consists of an encapsulated aqueous solution in contrast to that of micelles whose interior comprises the hydrophobic alkyl chains of the surfactant. The surfactant vesicles are much larger, more rigid (less fluid), and more static aggregate entities, particularly at temperatures below their phase-transition temperature.[151] Although vesicle aggregate structures are in equilibrium with their monomer, in most instances, the monomer concentration is fairly low (in range 10^{-5}–10^{-10} M).[152] Thus, the rate of exchange of monomers between the bilayer and surrounding solution is slow (minutes to hours).[18,152] Once formed, the vesicle aggregates cannot be destroyed by dilution, whereas micelles are destroyed. Vesicles, owing to their dimensions, can solubilize a larger number of analyte molecules per aggregate entity compared to micelle systems. In addition, molecules/analyte species may be entrapped within the inner water pool of vesicles for extended periods of time (days and weeks).[147] Of course, one disadvantage of vesicle/liposome systems is that their preparation is more complicated and less convenient compared with that of micelles. In addition, one must be aware of the possibility of aging effects due to vesicle–vesicle fusion, etc.[149,151,153]

Several monographs are devoted to the topic of liposomes, their preparation, characterization, and medical-related applications.[141,154,155] In addition, several articles discuss, compare and contrast the features of vesicle-organized media relative to surfactant micelles and CDs with respect to their usefulness in luminescence analysis.[156,157]

2.2 Cyclodextrin Systems

CDs (also referred to as *cycloamyloses*) are naturally occurring macrocyclic oligomers. They consist of six or more linked glycopyranose moieties and are doughnut-shaped molecules. The CDs differ in the number of glucose units they possess, with the designation alpha- (α-CD), beta- (β-CD), and gamma-CD (γ-CD) containing six, seven, and eight such units, respectively. The internal diameters and depths of the CDs are 4.5–6.0 and 4.5 Å for α-CD, 6.0–8.0 and 7.0 Å for β-CD, and 8.0–10.0 and 7.0 Å for γ-CD. The interior of the torsos of CDs is relatively apolar relative to water and is therefore capable of including a variety of guest analyte molecules.[13,18] The interior volumes are 176, 346, and 510 $Å^3$ for α-, β-, and γ-CD, respectively.[13,158] For comparison, the micellar hydrophobic volume for SDS, CTAC, and Triton X-100 are 21 000, 50 400, and 73 600 $Å^3$, respectively.[159] Also, in contrast to bile salt and surfactant micellar and vesicle aggregate systems, the CDs are chemically and conformationally stable, permanent molecular entities. Thus, CDs are more robust and durable in comparison and can be employed in a variety of solvent systems since there is no monomer ⇔ aggregate equilibrium involved as in the formation of micellar aggregates. These cyclic oligosaccharides are well known to be able to include a wide variety of guest molecules in their toroidal cavity and alter the physicochemical

properties of such guest species.[13,18,160–162] During the past decade, a variety of modified CDs have been prepared, many of which exhibit enhanced (or more selective) binding ability including enantioselective binding.[163–165]

Several monographs provide much more detailed information on CDs along with their properties and applications.[13,160–162,165]

Table 2 compares and contrasts these different organized micelle, vesicle, and CD assembly systems in terms of some of their properties and features.[18,166–168] Additional information on and comparisons among these different membrane mimetic agents can be found in an excellent monograph by Fendler.[18]

2.3 Summary of Selected Properties of Organized Assemblies

The ability of organized assemblies to solubilize solutes, to alter their microenvironment and effective concentrations, and hence to affect their reactivities, product distributions, stereochemistries, ionization constants, and redox potentials has been exploited in a number of chemical analysis applications.[9–14,94,125,166] The influence of the medium upon the energy of electronic states and solvatochromic shifts has been the topic of several reviews.[1–8,167–170] Organized assembly systems solubilize and bind various types of organic molecules in aqueous solutions. Fluorescence probe techniques (*see* **Absorption and Luminescence Probes**) have provided much valuable information about the microenvironment of ordered media (i.e. their apparent viscosity, polarity, etc.), which in turn allows conclusions to be made concerning the structure, location, and dynamics of molecules solubilized in such organized systems.[1–8,18,171–176] This section will summarize some of these more important general features, as they pertain to enhancing the performance of analytical fluorescence measurements.

2.3.1 Solubilization Ability

As illustrated in Table 3, the aqueous solubility of sparingly water-soluble organic compounds can be increased by the addition of organized assemblies to the aqueous solution.[42,94,177–185] The solubility of hydrophobic compounds in water can be dramatically enhanced by the addition of a surfactant to

Table 2 General comparison of the organized assembly systems[a]

Characteristic feature/property	Aqueous normal micelles	Bile salt micelles	Vesicles/liposomes	CDs
Constituents	Various synthetic surfactants	Bile salt surfactants	Lipids and surfactants	Various CD molecules
Method of preparation	Dissolution of surfactant in water (the surfactant concentration must exceed the CMC)	Dissolution of bile salt in water (bile salt concentration must exceed the CMC)	Ultrasonication, injecting thin lipid films into water, injecting ether or alcohol solutions of lipids into water, gel filtration of lipid–detergent micelles	Dissolution of the CD in water
Weight-averaged molecular mass	2000–6000	–	$>10^7$	970–1300
Diameter (Å)	30–60	20–40	300–5000	4.7–8.3
General stability	Weeks, months	Weeks, months	Days, weeks	Months
Kinetic stability (exit rate of monomer, s)	ca. 10^{-5}	–	>Seconds	Not applicable, bonded entity
Effect of dilution with water	Micelle destroyed if the surfactant concentration is less than the CMC	Micelle destroyed if bile salt concentration is less than the CMC	Unaltered	Unaltered
Number of solute molecules taken up per assembly	Few	Few	Large	Typically 1 or 2
Solute solubilization site(s)	Surface, Stern layer, in vicinity of polar head groups	In vicinity of either polar or nonpolar areas, polar head group	Inner aqueous pool, either or both sides of the polar surface, within the bilayer	Interior cavity of CD or near hydroxyl groups of the outer rim of the CD molecule

[a] Data taken from the literature.[18,166–168]

[b] CPC refers to cetylpyridinium chloride.

the aqueous solution.[21,94,177–203] Such enhanced solubilization is due to the formation of micelles by the surfactant, because below the CMC little increase in solubility is observed, yet above the CMC the increase in solubility is typically directly proportional to the surfactant concentration.[94,178,190] The absolute solubility of a solute in a micellar system depends upon the specific experimental conditions (surfactant concentration, presence and concentration of other additives, pH, temperature, and nature of the solute).[94,192] In addition, the solubilization power of surfactant aggregates depends upon the shape of that micelle entity (spherical, rodlike, etc.), with the solubilization capacity being proportional to the respective micellar volumes.[193] The uptake of

solutes into the micelle can change the physical state of the micelle and result in changes in the physical properties of the system.[94] As in the situation with the surfactant monomer, the solubilized solute is not rigidly fixed in the micelle. Instead, it can move about within the micelle aggregate and also is in constant dynamic equilibrium with the bulk aqueous phase. Almgren et al.[178] have described the dynamic and static aspects of solubilization of neutral solutes in ionic surfactant micellar solutions. In contrast to the solubility of organic hydrocarbons in hydrocarbon surfactant micelles, their solubility in perfluorocarbon micelles appears to be somewhat limited.[194]

As illustrated by the data in Table 3, the presence of micelle assemblies can enhance the solubility of sparingly soluble solutes by several orders of magnitude. As for some other examples, the solubility of phthalimides increases by approximately an order of magnitude in 0.10 M SDS micellar solutions compared with the solubility in pure water.[195] The aqueous solubility of α-terthiophene is $<10^{-7}$ M. However, aqueous solutions containing 38 μM α-terthiophene could be prepared in the presence of surfactant CTAC, dodecyltrimethylammonium chloride (DTAC), SDS, or Triton X-100 micellar media.[159] The presence of cationic CTAB micelles increases the solubility of folic acid in water by a factor of 216.[184] Most metal ion complexes of oxine (8-hydroxyquinoline) and its derivatives are insoluble in aqueous solution; however, these can be solubilized in surfactant micellar media.[196] Cholesterol monohydrate's solubility in aqueous micellar NaTC is ca. 90 times greater than that in bulk aqueous solution.[119,197]

Likewise, surfactant vesicle/liposome systems can enhance the solubility of organic compounds. For instance, the aqueous solubility of bilirubin-IXα is 9×10^{-8} M. However, concentrations up to 1.0×10^{-5} M were prepared in aqueous solutions containing 200 μM PC vesicles.[198] Bilirubin's solubility in the bile salt sodium cholate (NaC) micellar medium was reported as 30 mM.[125,199] Although the flavonoid baicalein as well as coomassie brilliant blue dye–CTAB detergent complexes are insoluble in water, they can be solubilized in phospholipid vesicle membrane media.[200,201] Nile red is sparingly soluble in water ($<1\,\mu g\,mL^{-1}$), but very soluble in aqueous micelle or vesicle solutions and organic solvents.[202] Fluorescence spectroscopy has been employed to study the solubilization of ketoconazole and griseofulvin in different bile salt micelles.[203]

The presence of CDs also generally increases the solubility of organic compounds in water, but this depends on the solute and the CD.[13,160,161] For instance, the solubilities of benzoic and aliphatic carboxylic acids were increased in the presence of α- and β-CDs, whereas the solubilities of carboxylic acids containing bulky groups were not appreciably affected.[161] The solubility of the flavin, lumichrome, and carbazole alkaloids in water increases with an increase in the concentration of β-CD.[204,205] The presence of 10 mM β-CD enhanced the aqueous solubility of *syn*-bimanes by ca. 10%.[206] In the presence of 3 mM β-CD, the solubility of lumichrome is threefold greater than in bulk water alone. However, the solubility of hydrophobic molecules in CDs is poor compared with other organized assemblies, such as aqueous micelles, and this factor is considered by some to be a serious disadvantage of CD systems.[207] In some cases, analyte-included CD complexes can precipitate from solution, especially from more concentrated stock solutions.[185,208] The solubility product and solubility of CD inclusion complex precipitates as well as requirements for formation of such precipitates have been reported.[209,210] CDs have been employed in preparation of pharmaceutical formulations not only to enhance solubility, but also to increase the permeation and bioavailability of drugs in biological systems.[211–213] However, the utilization of derivatized CDs, which are themselves more water soluble, generally improves their solubilization capacity. For instance, complexation of an indolinonic nitroxide radical with randomnly methylated β-CD served to improve not only the nitroxide's aqueous solubility, but also its photostability.[214]

In some situations, organized assemblies have been employed merely for solubilization purposes in fluorescence assays. For example, the surfactant Triton X-100 was employed in the isolation of membrane-bound proteins owing to its ability to disrupt membranes and solubilize proteins without denaturation. The subsequent assay of the protein was achieved by reacting it with fluorescamine and monitoring the FI (excitation and emission wavelengths, $\lambda_{ex} = 390$ nm, $\lambda_{em} = 475$ nm) of the product.[215] The presence of the Triton X-100 solubilization agent did not affect the fluorimetric measurements.

A sensitive fluorescent assay for lipase activity utilized egg PC liposomes or a mixed bile salt/liposome system to solubilize the nonfluorescent substrate 4-methylumbelliferyl butyrate.[216] Triacylglycerol lipase was incubated in this medium, and after termination of the analytical reaction the FI measured ($\lambda_{ex} = 365$ nm, $\lambda_{em} = 450$ nm). The detection limit of lipolytic activity was $10\,\mu M\,h^{-1}$ in the mentioned organized assembly medium.[216]

A simple, sensitive, and rapid assay for vitamin K_1 was developed which uses the photo-oxidation of glucose sensitized by vitamin K_1.[217] The hydrogen peroxide generated in the photochemical reaction was determined through the iron(II)-catalyzed oxidation of benzoic acid

to form hydroxybenzoic acid isomers, which fluoresce. The use of Triton X-100 micelles was employed in order to overcome the problem of the poor water solubility of the phylloquinone. In addition, in the absence of TX-100, the ferrous ion is rapidly oxidized to ferric ion, which is unstable in basic aqueous media and slowly precipitates (owing to the formation of the oxide and/or hydroxide salts), which causes signal instability and clogs the flow-injection analysis (FIA) tubing. The presence of the Triton X-100 micellar medium successfully avoids these deleterious effects and problems.[217] CTAC micelles were incorporated into a fluorescent method for the simultaneous determination of fat-soluble (vitamins A and E) and water-soluble vitamins (B_1, B_2, and B_6)[187] (*see* **Vitamins: Fat and Water Soluble, Analysis of**).

Hence, the solubilization property of organized assemblies allows one to work directly in an aqueous phase without the need for organic or mixed aqueous–organic solvents. In fact, the utilization of organized assembly systems and their solubilization ability can aid analyte sample preservation and storage[218] (*see* **Sampling and Sample Preparation in Process Analysis**; **Sample Preparation Techniques for Elemental Analysis in Aqueous Matrices**). Two of the more frequent and serious difficulties encountered when working with real-world samples concern analyte loss due to its adsorption on the surfaces (walls) of the storage container or to its interaction with organic particulate matter or soil sediments (humic materials, bentonite, etc.). The use of surfactant micellar media can obviate both problems. For example, one study found that the presence of Brij-35 surfactant in the sample solution was as effective as 40% (v/v) acetonitrile in preventing loss of polycyclic aromatic compounds (PACs) due to adsorption on the surface of borosilicate glass, white polyethylene, or polytetrafluoroethylene (PTFE) containers.[219,220] The addition of nonionic Triton X-114 was also found to enhance PAC recovery during sample preconcentration.[221] In a Brij-35-modified procedure for determination of 13 polycyclic aromatic hydrocarbons (PAHs), it was reported that the Brij-35 micellar solutions containing these PAHs were stable for at least 24 h, except for those of naphthalene, anthracene, and acenaphthene, whose FI decreased ca. 15, 17, and 12%, respectively, over 24 h.[222] Enhanced stability of PAHs in the presence of the nonionic surfactant polyoxyethylene-10-lauryl ethers has also been reported.[223] With biological/clinical samples, it was noted that the addition of SDS was effective in preventing the sticking of protein to the tubes and pipet tips, leading to more reproducible results in a protein fluorescence quantitation based upon reaction with *o*-phthaldialdehyde.[224] The nonionic surfactant polyethylene (20) sorbitan monolaurate was demonstrated to prevent DNA adhesion to the surface of the containers.[225] Likewise, the use of micellar sodium dodecylbenzenesulfonate (SDDBS) prevented the adsorption of different metal–porphine chelates on glassware surfaces.[226]

It has been reported that the presence of CDs can prevent (or reverse) the effects of sample adsorption of analytes to the walls of the container. For example, addition of β-CD led to the dissolution of pyrene that had been adsorbed on the walls of the glassware.[227] Addition of solutions of CDs also successfully sequestered (redissolved) organic molecules from the walls of glass tubes on which they had been deposited into the aqueous solutions.[228] Memory effects due to adsorption of metal ions, such as Eu^{3+}, on the walls of glass containers during storage of stock solutions have been reported.[229] Such effects might be diminished or eliminated if surfactant micelles or CDs were added and present in the stock solution.

2.3.2 *Solute Incorporation and Binding to the Organized Assembly*

Solute binding to organized assemblies has resulted in widespread applications of such systems in pharmaceutical chemistry, catalysis, chemical analysis and separation science, and food technology, among others.[9–13,18,94,160,230]

The binding association of a solute molecule with a micelle may be divided into several stages corresponding to the different sites of possible interaction: the bulk solution, the micelle outer surface region, and the more hydrophobic micelle interior (refer to possible binding sites as depicted in Figure 1). In the initial stage, the rate of interaction is the bulk solution encounter rate, which is typically near the diffusion-controlled limit (i.e. ca. $3 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$),[178,231–233] particularly when the solute and micelle species are of opposite charge. Solute protonation or deprotonation may occur in the second step since the micelle surface region pH is typically different, sometimes by ca. 2 pH units, from that of the bulk aqueous solution phase.[233,234] The rate of proton transfer in micelle systems is also typically diffusion controlled, so that this is not ordinarily the rate-determining step.[233,235] The final stage of incorporation represents the complex set of interactions resulting from hydrophobic and/or electrostatic forces as the solute occupies its preferential averaged-binding site, either in the micellar core or surface regions or in some intermediate position. This last step is typically the rate-limiting one for solute incorporation. For instance, when neutral dye molecules, such as methyl red (MR), methyl orange (MO), or pyridine-2-azo-*p*-dimethylaniline (PADA), are incorporated into SDS or CTAB micelles, the rate constants are in the

10^6 dm^3 mol^{-1} s^{-1} range.[233] However, the rate constants increase to the diffusion-controlled limit in the cases where these dyes or organic molecules and the micelles involved are oppositely charged. This was rationalized in terms of the electrostatic forces becoming dominant in the final interaction step. Similarly, the rate can be increased by increasing the hydrophobicity of the solute molecule or the micelle.[233] As noted by Quina, ''small molecules and ions can migrate rapidly in and out of the aggregates, while those incorporated in the microaggregate can migrate within the aggregate.''[176] Solute incorporation rate constants (entrance rates) are typically in the range of 10^8–10^{10} M^{-1} s^{-1}, while the solute rate constants for exit from the micelle (exit rates) are in the range 10^2–10^8 s^{-1} depending upon the specific solute–surfactant micelle combination.[236] Since the entrance rate constants are generally near diffusion controlled, it is the exit rate constant that typically dictates the magnitude of the degree of solute binding to the micelle.[236,237]

Solute complexation with CDs is also a dynamic process.[13,18] The entry and exit rate constants for the complexation of naphthylethanols with β-CD have been determined.[238] Rate constants for entry and exit of guest molecules into such CD hosts are typically of the order of 10^8–10^9 M^{-1} s^{-1} and 10^5–10^7 s^{-1}, respectively (for 1 : 1 complexation stoichiometry).[18,238] To a first approximation, the strength of binding correlates with the fit of the solute molecule in the CD cavity.[13,18] The interior of the doughnut-shaped CD molecule is lined with oxygen and CH groups, providing a relatively hydrophobic binding site for molecules of appropriate size that can fit the particular CD's cavity. One exterior side of the torus contains the primary hydroxyl groups, while the other side contains a number of secondary hydroxyl groups on the C-2 and C-3 atoms of the glucose moieties. Thus, these hydroxyl groups offer hydrogen-bonding sites to the portion of a solute molecule that possesses an appropriate hydrogen-bonding moiety.[18] Since CDs (and also the bile salt micelles) are chiral entities, differences can be observed in the binding constants for an enantiomeric pair of analytes for these two organized assembly systems.

In synthetic surfactant vesicle or natural liposome aggregate systems, there are several possible analyte binding sites that exhibit a range of polarities. At the water-pool–head-group interfacial regions, the sites are relatively hydrophilic, whereas more hydrophobic (and ordered) sites are available within the hydrocarbon interior of the bilayers.[18] Of course, between these two extremes lie sites of intermediate hydrophobicity. Figure 2 depicts some of these potential binding sites for a liposome system, illustrating the binding of the relatively

Figure 2 Artistic representation showing the bilayer structure of an entire small unilamellar vesicle (liposome) of egg yolk PC, along with an upper expanded view of possible solute binding sites. A more polar solute, such as benzyl alcohol, would be located near the surface phospho head group areas, whereas the less polar *n*-propylbenzene prefers to bind to the more hydrophobic interior region. (Adapted with permission from E. Okamura, M. Nakahara, *J. Phys. Chem.*, **103**, 3505–3509 (1999). Copyright 1999, American Chemical Society.)

polar benzyl alcohol and less polar *n*-propylbenzene molecules to an egg yolk PC SUV.[239] Consequently, it should not be surprising that, depending on the luminescent probe employed and its specific binding site, a number of possibilities for interaction of solutes of differing hydrophobicity (or polarity) within the vesicle interior exist.[240–243]

The fluorescence technique has proven to be a very useful means by which to determine the binding constants for equilibrium interaction of an analyte, A, with a particular organized assembly, OA, system Equation (1):[13,173,244–249]

$$A_W + OA \xleftrightarrow{K_B} A_{OA} \tag{1}$$

The equilibrium or binding constant, K_B (M^{-1}), is given by Equation (2):

$$K_B = \frac{[A_W]}{[A_{OA}]}[OA] \tag{2}$$

where $[A_W]$ and $[A_{OA}]$ denote, respectively, the analyte substrate molar concentration in the aqueous and organized assembly phases, and $[OA]$ is the concentration of the organized assembly under consideration. For micellar systems, the concentration of micellized surfactant is equal to the total surfactant concentration minus that surfactant's CMC. For micellar media, this solute–micelle binding constant, K_B, can be related to the partition (or distribution) coefficient, P, for distribution of the solute between the micellar and bulk aqueous phases, by Equation (3):

$$K_B = (P - 1)v \quad (3)$$

where v is the partial molar volume of the surfactant.[12,248,250]

The literature contains a plethora of data regarding the interaction and binding of solute (analyte) species to organized assembly systems.[249–317] Some representative data (in the form of binding constants or partition coefficients) for the interaction of ions and organic species with different organized media is presented in Table 4. As can be observed, the same analyte can bind to greatly differing extents to different organized assembly systems. Orders of magnitude differences in binding constants can exist for the same general type of organized assembly system. Solute binding constants and residence times in aqueous micelles are of the order of 10^3–$10^6\,M^{-1}$ and 10^3–$10^5\,s^{-1}$, respectively.[18] For example, the binding of pyrene to different surfactant/bile salt micelles ranges from ca. $1.5 \times 10^5\,M^{-1}$ for NaC to $1.0 \times 10^7\,M^{-1}$ for

[a] P refers to the partition (or distribution) coefficient, with values given in parentheses.
[b] Refers to tris(2,2′-bipyridinium)ruthenium(II) cation.
[c] Refers to 1-anilonaphthalene-8-sulfonate.
[d] Refers to egg PC.
[e] Refers to 3,3-dimethyl-2-phenyl-3*H*-indole.
DPH, 1,6-diphenyl-1,3,5-hexatriene; DTAB, dodecyltrimethylammonium bromide; DMA, dimethylaniline; SB-12, sulfobetain-12; phen, 1,10-phenanthroline; ANS, 8-anilino-1-naphthalenesulfonate, MB, methylene blue; TDSS, sodium tetradecyl sulfate.

binding to CTAB micelles (Table 4). A comprehensive compilation of solute–micelle binding constants (partition coefficients) is available.[318]

In the case of micellar media, linear solvation free energy relationships of the form shown in Equation (4) have been reported:

$$\log K_B = c + a\sum\alpha + b\sum\beta + s\pi_2 + rR_2 + v\left(\frac{V_x}{100}\right) \quad (4)$$

in which the binding of solutes to a specific surfactant micelle is related to the medium-independent parameters for solute hydrogen bond acidity $\left(\sum\alpha\right)$ and basicity $\left(\sum\beta\right)$, excess molar refraction (R_2), dipolarity (π_2), and volume (V_x).[255] For the cationic surfactants DTAB and CTAB, nonionic surfactant Brij-35, and anionic SDS, solute incorporation and binding to the micelle is dominated by the V_x term (positive, reflecting the hydrophobic effect) and the $\sum\beta$ terms (negative, implying that bulk water is a better hydrogen-bond donor than the micellar solubilization site).[255] The contributions of $\sum\alpha_2$ and R_2, although smaller, were reported to vary in a chemically satisfying manner with the surfactant charge and structure.[255] Such linear salvation free energy relationship (LSER) relationships allow the determination of the relative importance of these factors in binding to a specific surfactant micelle and also allow the estimation of the actual solute binding constant for a specific surfactant micelle provided that the solute's

required parameters are known. Such an approach should also be applicable to synthetic surfactant vesicle or natural liposome aggregate systems. A similar approach utilizing the transition energy of fluorescent probes in CTAB, SDS, and Triton X-100 was conducted, and the aforementioned solvatochromic parameters determined for these three micellar systems.[320] However, the values were determined using a rather limited number of probe molecules.

Table 4 also includes solute–CD binding constants for formation of 1 : 1 inclusion complexes. Several monographs and reviews summarize methods utilized to determine solute–CD binding constants and also provide binding constant data for a wide range of solutes.[13,253,296,319,321,322] On the basis of the examination of 569 such complex systems, Equation (5) was found to provide reasonable estimates of the magnitude of the CD binding interaction:

$$\log K_B = -1.74 - [Z] + 0.032(\Delta A) \qquad (5)$$

where $[Z]$ incorporates solvent–solute (solvation) and solute–solute interactions and ΔA is the decrease in nonpolar surface area (in $Å^2$ per molecule) of the substrate that is exposed to the solvent upon binding to the CD cavity.[319] A phenomenological theory has been proposed for estimation/prediction of the magnitude of the binding constants for formation of 1 : 1 α-CD–solute inclusion complexes in aqueous solution at 25 °C.[289,319]

In addition to the selected data presented in Table 4, binding constants for the inclusion complexation of 56 mono- and 1,4-disubstituted benzenes with α- and β-CD have been reported.[261] Binding constants for the interaction of naphthalene and some of its mono- and dimethyl derivatives with α-, β-, and γ-CD are available.[251] The binding constants of 13 flavonols to β-CD under acidic and basic conditions have been reported.[323] It is evident from the data in Table 4 that the three different CDs can have large differences in the magnitude of the binding constant with respect to the same solute (as a consequence of the steric requirements and size of the solute in relation to the size of the specific CD cavity). It is important to note that the same solute can bind differently (positionally) to the three CDs.[263,324] For instance, methyl salicylate binds to α- and β-CD in different geometries.[263] In the former case it was postulated that the ester and hydroxyl groups were buried in the interior cavity, whereas in the latter case the phenyl end of the methyl salicylate molecule binds in the cavity. The magnitude of solute–CD binding constants typically decreases with an increase in temperature.[289] For instance, the binding constant for interaction of 1-naphthyl acetate with β-CD is 463 M^{-1} at 15 °C and only 134 M^{-1} at 40 °C.[325]

The $CD : solute$ stoichiometry and magnitude of binding interaction can also be impacted by the presence of other organic additives, depending on the additive's hydrophobicity and spatial volume.[173] For example, it was noted that the binding constant for interaction of 1-naphthol with β-CD decreased if methanol or ethanol was added to the aqueous solution.[272] However, Nakajima[326] demonstrated an increased binding constant of pyrene and β-CD in the presence of ethanol. Warner et al. have also reported that the presence of small amounts of other additives can impact the magnitude of CD–aromatic solute binding constants. For example, the addition of 1.0% of alcohol greatly enhances the binding of pyrene to CDs.[173,257] Dramatic enhancements of fluorescence quantum yield with coumarin laser dyes have been observed upon inclusion by β-CD in aqueous solution, but only when small amounts of organic cosolvents were also included.[327] This was interpreted in terms of the fact that the small organic molecules displace water (which has a pronounced fluorescence quenching ability) from the CD cavity and act as space fillers to enhance binding. Likewise, addition of cyclohexanol as cosolvent to aqueous solutions of γ-CD containing 2-naphthyloxyacetic acid (2-NAA) resulted in an increase in the FI of 2-NAA.[328] As 1-butanol is added to aqueous solution containing the γ-CD–pyrene 1:2 complex, it displaces one of the pyrene molecules from the CD cavity to form the 1 : 1 : 1 CD–pyrene–butanol complex.[329] The binding interaction between sodium salicylate and β-CD was also increased owing to the presence of various alcohols.[262] However, in this instance, the addition of the alcohol to the system resulted in a decrease in the FI observed from salicylate.

The nature of the bulk solvent as well as charge on the CD (or solute) also impacts their solute binding ability. For instance, the interaction of ketocyanine dyes with β-CD dissolved in aqueous and dimethylformamide (DMF) as bulk solvent is different. The equilibrium binding constants were found to be greater for ketocyanine binding to β-CD that was dissolved in the nonaqueous media. An investigation of the binding of piroxicam to neutral β-CD and a charged β-CD revealed that the charged form interacted more strongly with this analyte.[330,331] The neutral form of the drug celecoxib was found to bind to β-CD approximately four times better compared to its ionized form.[332]

In the case of CDs, buffer and salt components employed to adjust the pH and/or ionic strength influence the equilibrium constant for the particular CD–solute inclusion complexation process.[13,333] For instance, the binding constant for interaction of 3-hydroxy-2-naphthoic acid with β-CD at pH 5 and 25 °C ranged from 264 M^{-1} in the presence of sodium perchlorate to 1260 M^{-1} in

the presence of sodium chloride (ionic strength 0.1 M) (the binding constant in the absence of any salt was 1083 M^{-1}).[333] Thus, differences in the strength of analyte binding to CDs could also impact and influence the magnitude of fluorescence observed. Hence it is important to compare only similar systems and, in analytical measurements, to ensure that such variables are held constant.

Likewise, the addition of additives can alter the FI of analytes bound to vesicle/liposome assemblies. For example, the FI of 1,6-diphenyl-1,3,5-hexatriene (DPH) in DPPC vesicles is reduced by over 50% due to the presence of added ethanol.[334] The ethanol causes the DPPC aggregates to undergo the L_β to $L_\beta I$ phase transition which alters the location and binding environment of the DPH solute with a resultant decreased fluorescence efficiency. Alternatively, surfactants can be added to produce similar effects. Alterations in temperature can also have dramatic effects on the magnitude of solute partitioning into vesicle/liposome systems.[295,335] Differences in the vesicle size (which varies with the preparation method employed) can affect solute binding. For instance, the magnitude of the binding constants for interaction of *n*-heptanethiol with DODAC vesicles were 500, 1200, and 2800 M^{-1} for vesicles whose hydrodynamic diameters (size) were 2850, 520, and 220 Å, respectively.[336] Hence all of these factors that influence analyte binding to vesicle/liposome aggregate systems can in turn alter the maximum fluorescence emission intensity observed from those solutes as well.[337]

With respect to solute binding to a particular organized assembly, it should be recognized that there is a distribution of locations instead of a unique specific binding location in the assembly (i.e. a heterogeneity of binding sites exists, each site being characterized by a different microenvironment). In addition, there is the possibility of organized assembly heterogeneity (a distribution of micelles or vesicles of different aggregation numbers, etc.). Ordered lipid systems are thought to be heterogeneous in the sense that fluorescent solutes, when embedded in such ordered lipid media, are situated within different sites of different ordering and mobilities.[338] Hence this multitude of possible interactions during the excited-state lifetime of the solute in such an organized system results in a multitude of deactivation channels of the excited state, leading to distributions in such fluorescence properties as lifetimes, quantum yields, etc.[339–343] Huang and Bright[342] noted that for micellar media, there could be several contributions to such observed distributions including (i) water gradients, (ii) micelle polydispersity, and (iii) compositional diversity within the micelles.

All of the binding constant data reported for the CD–solute combinations in Table 4 were for the 1 : 1 complexes (one solute molecule bound per CD molecule). However, in some situations, higher-order complexation can occur, with 1 : 2, 2 : 1 or 2 : 2 CD:solute complex stoichiometry being reported.[265,296,317,321,344,345] Coumarin 153 forms both 1 : 1 and 1 : 2 complexes with methylated β-CD.[346] The size of the particular CD cavity serves to impose possible steric restrictions with respect to the number of analyte molecules which can be bound. For example, the larger-diameter γ-CD can accommodate two pyrene molecules, whereas in the cases of binding to α- or β-CD, only one pyrene is bound.[227] Such results indicate that an important factor in solute binding to CDs in aqueous solutions is the size of the analyte in relation to the cavity dimensions of the particular CD.

In the case of micelles (or vesicle systems), an useful means to assess the degree of solute occupancy is to assume that the analytes distribute among the micelle/vesicle aggregates according to Poisson statistics.[1,5,7,8] The probability of a micelle containing x analyte molecules is given by Equation (6):

$$P(x) = \mu^x \frac{e^{-\mu}}{x!} \tag{6}$$

where μ is the stoichiometric mean number of analyte molecules per micelle (i.e. [analyte]/[micelle]) and $P(x)$ the probability of a micelle with an occupation of x analyte molecules[26,316,347] (for a brief discussion of the distribution of solubilized molecules among micelles, see Miller[348]). The concentration of micelles [micelles] is given by Equation (7):

$$[\text{micelle}] = \frac{C - \text{CMC}}{N} \tag{7}$$

where C is the surfactant concentration and N is the micelle aggregation number. As an example, for a solution of an analyte whose concentration is 1 mM in a 0.10 M SDS micelle medium, the average number of analyte molecules per SDS micelle, μ, would equal 0.6 (assuming an aggregation number of 60 for SDS). For this example, $P(0) = 0.549$ (54.9% of the micelles contain no analyte molecule) and $P(1) = 0.329$ (32.9% of the SDS micelles contain one analyte molecule), and 12.2% of the micelles would contain two or more analyte molecules.[347] By contrast, if the analyte concentration is only 1.0×10^{-5} M, then only 0.3% of the occupied micelles (0.6%) would contain two or more analyte molecules.[89]

As another example, for a micelle concentration of 1.0 mM and an oxygen concentration of ca. 0.10 mM, $\langle O_2 \rangle = 0.1$; thus 90% of the micelles will be free of oxygen.[7] As a consequence, analyte molecules bound to the micelles would be "protected" from oxygen quenching. Consequently, manipulation of the concentration of micelles in relation to that of the analyte

(or analytical reagents/impurities present) is possible so as to prevent multiple analyte/solute/impurity occupation of the micelles. At any given analyte concentration, an increase of concentration of micelles will serve to decrease μ. A relatively high surfactant micelle to analyte concentration ratio will serve to ensure that the probability of any one micelle containing two or more analyte (or analyte–solute or analyte–impurity, etc.) molecules is very low. This in turn eliminates (or greatly reduces) the possibility of formation of the dimeric form of the analyte molecule (which typically are not or weakly luminescent) or diminishes other solute/impurity quenching of that analyte.

In addition, for situations in which both analyte and quencher bind to the micellar aggregate, the quenching efficiency typically decreases with increasing surfactant concentration.[266] This is a consequence of the fact that increasing surfactant concentrations result in formation of a greater number of micelle aggregate species; thus, the probability that any one micelle has both the analyte and quencher bound to it decreases. Thus, impurity quenching (of analytes) can be suppressed in micellar solutions provided that the fluorescent analyte and the impurity molecules are likely to be solubilized in different micelles. In fact, in one report it was noted that the fluorescence quantum yield for 9,10-dimethylanthracene in ethanol was lower compared to that in the literature and that this was likely due to impurities present in the chemical.[349] However, in micellar solutions, the anticipated value was observed despite the presence of that impurity. This clearly demonstrates that impurity quenching can be suppressed in micellar solutions.

2.3.3 *Effect of Organized Assembly Systems upon the Reaction Rate and Path*

Aqueous organized assembly systems often induce changes in a wide variety of ground- and excited-state reactions. Reactions and the position of chemical equilibrium in such systems often proceed in a manner very different from that observed in homogeneous bulk solvents owing to the altered microenvironment and concentration effects in the organized medium.[7,18,161,350,351] It is well known that surfactant micellar systems or CDs can impact (either accelerate or inhibit) many types of chemical reactions.[18,94,160,161,350–353] An excellent recent review article discusses reactions in micellar systems[350] and an exhaustive compilation of altered reactivities in different ordered assembly systems is provided in monographs by Fendler.[18,353] A model (pseudophase ion exchange (PPIE)) has been developed for ionic micellar solutions, which is capable of describing and predicting most ionic micellar effects on reaction rate and equilibria over a wide range of experimental conditions (pH, detergent, added salt, etc.).[354] A review article summarizes and discusses the use of CDs to mediate a wide range of different types of organic reactions.[355]

As examples of ordered media effects, reactions involving the cleavage of phenyl esters, decarboxylation of cyanoacetates, and oxidation of α-hydroxyketones were accelerated by factors of 300, 44.2, and 3.3, respectively, in the presence of CDs compared with that in their absence.[161] Decarboxylation reactions were also enhanced in the presence of micellar systems. For instance, the presence of CTAB, Triton X-100, and SDS enhanced the rate of decarboxylation of 5-amino-1,3,4-thiadiazole-2-carboxylic acid by factors of 5.0, 5.7, and 1.3, respectively.[18] Cationic CTAX micelles caused an increase in the rates of reduction of the carbonyl group of steroids by factors of 2.2–7.8, depending upon the steroid's structure.[94] In addition to alteration of the rates of reactions, the product distribution (including stereochemistry) can be affected by the presence of organized assemblies such as CDs or micelles.[94,161] The photodecarboxylation reaction of ketoprofen occurs with a decreased rate in the presence of β-CD compared to that in aqueous solution. Also, in the β-CD medium, an additional photoreaction was observed.

Review articles discuss the factors that affect the kinetics of photoreactions in organized assemblies and the topics of photochemistry in surfactant solutions and the fate of excited-state probes in micelles.[2–8,167–169,356–360]

The type and concentration of organized media can also have a profound effect upon different photochemical processes.[6,7,94] For instance, the quantum yield of trans $\rightarrow$ cis photoisomerization of (dibutylamino)stilbazolium butanesulfonate was found to be almost 2 orders of magnitude greater in micelle and vesicle ordered media compared to that in bulk water.[32] In contrast, the yield for the trans $\rightarrow$ cis photoisomerization of azobenzene in the presence of CDs was roughly only half of that observed in 80:20 (v/v) water/methanol solution.[356] The rate constants for hydrolysis of cytotoxic pyronins is altered compared to that observed in a bulk alkaline medium.[357] For example, the presence of cationic CTAB micelles resulted in a threefold higher rate constant compared to that in aqueous solution, whereas the hydrolysis reaction was completely inhibited by anionic SDS micelles.

Vesicle/liposome systems can also alter reactivity. The second-order rate constants for the alkaline hydrolysis of *p*-nitrophenyl octanoate in the presence of DODAC or DODAB surfactant vesicle systems were 28–61 times larger than the rate observed in water in the absence of the amphiphile at the same pH.[336] The bimolecular

rate constant for the photooxidation reaction of 1,3-diphenylisobenzofuran with singlet molecular oxygen in the presence of zinc(II) phthalocyanine is roughly 2 orders of magnitude smaller in the presence of DPPC liposomes compared with that in ethanol solution.[361]

The rate and quantum yield of electron exchange between excited pyrene, P and dimethylaniline (DMA) (Equation 8):

$$DMA + P^* \longrightarrow P^- + DMA^+ \qquad (8)$$

to yield the pyrene anion and DMA cation has been examined in different media.[362] A continual decrease in the yield of the pyrene anion (ion yield of 1.0 in the presence of aqueous CTAB micelles) is observed on going from aqueous micelle to aqueous vesicle to swollen micelle to microemulsion systems, with no yield of ions observed in reverse micelles.[362]

The presence of β-CD reduced the initial rate of product formation in the photohydroxylation of 3-nitroanisole compared to that observed in homogeneous aqueous buffer solution.[259] Many organic molecules exhibit a greater degree of photostability in organized assembly media compared to the general behavior observed in organic solvents.[1–8,18,42,214] The observed rate constant for the second-order decay of mesitylthiyl radicals was 3000 times less in a 0.05 M SDS micellar medium than that observed in heptane.[363]

Quenching of excited states of molecules can be dramatically altered in the presence of organized media. Depending on the nature (size, hydrophobicity, or charge type if an ion) of the quencher and luminescent molecules in relation to the type (micelle, CD, vesicle, etc.), nature (neutral or ionic), and concentration of the organized media, either decreases or increases in quenching can be observed. In aerated solutions, the fluorescence lifetime of pyrene in pure water is shorter (126 ns) than in aqueous solutions of CTAC or SDS micelles (157–158 ns).[364] This was initially rationalized in terms of either a (i) lesser solubility of oxygen in the micelle relative to water, (ii) rate constant for oxygen-quenching of solubilized pyrene slower than diffusion controlled in bulk solution, or (iii) quenching of pyrene fluorescence by water.[364] Reasons (i) and (iii) were subsequently ruled out.

The main factor responsible for enhanced lifetimes in organized media thus appears to be decreased quenching constants. For example, the excited state of pyrene is quenched by oxygen molecules in bulk solvents. The bimolecular quenching rate constant is $1.1 \times 10^{10}\,M^{-1}\,s^{-1}$ in aqueous solution.[362] However, it is about an order of magnitude less in the presence of β-CD ($1.2 \times 10^{9}\,M^{-1}\,s^{-1}$). In the presence of a mixed organized system containing either SDS or CTAB and the β-CD, the quenching rate constant is further reduced to $6.0 \times 10^{8}\,M^{-1}\,s^{-1}$.[362] These results were rationalized as follows: The pyrene can bind to the cavity of the β-CD molecule, wherein it is somewhat protected from quenching by other molecules, such as oxygen, following its excitation. The addition of either SDS or CTAB results in the surfactant molecule also binding to the CD cavity, which leads to a more hydrophobic microenvironment for pyrene in addition to a greater binding constant and greater protection from quencher molecules. Similar results concerning resistance to oxygen-quenching of fluorescence for other organic solutes bound to organized assemblies have been reported.[42] Pyrene is also considerably protected from oxygen if present in DODAC vesicles.[146] In a comparative study of several micellar systems, the effectiveness of the protection of pyrene from oxygen-quenching (as given by the lifetimes of excited pyrene) was Brij-35 > SDS > surface-active crown ether decyl-18-crown-6.[365] The conclusions of another study indicated that nonionic surfactant micelles were more effective in protecting excited states of organic molecules from oxygen-quenching compared to ionic micelles.[366]

Likewise, 1 to 2 orders of magnitude reductions in the bimolecular quenching rate constants were observed for pyrene with the quenchers nitromethane, thallium(I) cation, copper(II) cation, and methyl viologen cation in the presence of these organized assemblies.[364] Thus, via the use of CDs, with or without added surfactants, it is possible to shield pyrene to various degrees from quenching interactions due to external species.[207] A nearly fourfold decrease in the quenching efficiency of iodide ion toward 2-naphthol was observed when the naphthol was bound to α-CD.[324] The presence of β-CD, which served to bind the methyl-2-aminobenzoate (MAB) solute, dramatically protected MAB against quenching by iodate ion. The fluorescence quenching of pyrene by *N,N*-DMA was diminished by a factor of ca. 7.5 in the presence of β-CD compared with that observed in the 50 : 50 (v/v) dimethylsulfoxide–water bulk solvent in its absence.[283] Therefore, the use of organized media can minimize or obviate detrimental analyte–solute (or solvent) interactions that otherwise might lead to quenching deactivation of the analyte's excited state[20]

However, if both fluorescent solute and quencher molecules are of appropriate size so that they both bond to one CD cavity, then the quenching interaction can be enhanced. For example, in the presence of β-CD, the fluorescence quenching of naphthalene, 1-methylnaphthalene, and acenaphthene by trimethylamine was greater by factors of 17, 91, and 280, respectively, compared to that observed in water at 25 °C.[367]

Metal cations are attracted as counterions to the surface of anionic micelles or vesicles and act as more

efficient quenchers, whereas anionic species are repelled and ineffective. The opposite would be true for cationic micelles or vesicles for which anions would be more efficient quenchers.[347] Hence, the use of appropriate micellar media can be utilized to achieve some selectivity against charged quenchers. For example, metal (or other) cationic species are repelled from cationic micelles and their quenching of micellar-bound solutes is thus ineffective. Likewise, anionic species would be repelled from anionic micelles and hence bind solutes protected from such quenchers. Consequently, through judicious choice of micelle (or other organized media), charge type (and concentration) in relation to the analyte, and quencher molecules, it is possible to either decrease or increase the quenching efficiency as desired.

The quenching effects of neutral species can also be diminished when luminescent species are bound to micelle systems. For example, the quenching of several aminobenzoic acid derivatives of aminoacylmonomethylamides by acrylamide in pH 7.4 phosphate buffer was decreased roughly by a factor of two in the presence of SDS micelles.[368] The lowering in quenching indicated a diminution in the rate of collisions between the aminoacylmonomethylamide compounds and the quencher acrylamide. Likewise, the quenching effects of iodide ion toward lumichrome was decreased about fourfold in the presence of β-CD.[204]

The utilization of organized media for examination of the mechanism of resonance energy transfer has been the focus of many studies. This is due to the importance of such energy transfer in solar energy conversions, photosynthesis, etc. The addition of different organized assemblies has been shown to enhance the efficiency of such energy transfer steps in a number of systems. For instance, efficient energy transfer from the excited state of acridine orange-10-dodecyl bromide (AOD) to methylene blue (MB) has been observed in the presence of SDS micelles.[369] In contrast, only very little sensitized fluorescence of MB was observed in ethanol as the bulk solvent. Enhancement of the efficiency of energy transfer is possible if the particular organized assembly binds the two species involved so that they are in close proximity. For some systems, it has been shown that vesicle or liposome systems are superior to micelles in this regard. The energy transfer from a donor oxacyanine dye molecule to the acceptor thiacyanine dye is 20–100 times more efficient in a cationic vesicle system than in CTAB micelles.[148]

The rate of energy transfer from excited $Tb(pdc)_3^{3-}$ (pyridine-2,6-dicarboxylate, pdc) to $Ln(pdc)_3^{3-}$ is very slow in bulk aqueous solution; however, association of these complex ions with CTAB results in rapid and efficient energy transfer.[370] The apparent second-order rate constant of energy transfer from 2-acetylnaphthalene to europium(III) ions in SDS micelles is 1 to 2 orders of magnitude larger than the value in homogeneous solution in the absence of SDS, depending upon the specific SDS and Eu(III) concentrations.[371]

In addition, enzyme-generated triplet species can transfer their energy to suitable acceptors and elicit sensitized emission in organized assemblies. For instance, the electronically excited state generated during the peroxidase-catalyzed aerobic oxidation of appropriate substrates efficiently led to fluorescence emission from acceptors like 9,10-dibromoanthracene or chlorophyll solubilized in CTAB, SDS, and Triton X-100 or Brij-35 micellar media.[372] It was noted that ''micelle-solubilized chlorophyll is an excellent detector of enzyme-generated triplet carbonyl species and the use of micelles make it possible to extend (this approach to study) other photobiologically important yet water-insoluble acceptors''.[372]

Hence it is possible to exploit such unique kinetic effects due to the presence of appropriate organized assembly systems in order to manipulate the rates of reaction for the purpose of enhancing the fluorescence performance; that is, the use of ordered media can catalyze otherwise slow analytical fluorescent derivatization reactions. Alternatively, one can employ such organized systems to inhibit or slow down undesired side or decomposition reactions in order to stabilize the desired fluorescent species.

For example, in a fluorescence assay for cyanide ion based on its reaction with 1,4-naphthaquinone-2-sulfonic acid to form a fluorescent product, the reaction time in the presence of CTAB micelles is only ca. 5 min compared to a reaction time of roughly 90 min in its absence.[373] The rate of phenolic oxidative coupling of morphine and related opiates to yield fluorescent products, utilized for postcolumn high-performance liquid chromatography (HPLC) detection, was increased in the presence of the nonionic surfactant Triton X-100.[374] In addition, the micellar medium protected the fluorescent product from further oxidation. The presence of the micellar system thus improved the stability of the system and detection limits possible relative to that observed in bulk solvent with no surfactant present. There are also other examples of micellar catalysis to speed up fluorescent reactions. In a method for determination of laccase activity, the apparent rate of oxidation of *o*-phenylenediame catalyzed by laccase was enhanced by Brij-35 micelles.[375] The detection limit was $0.07\ U\ L^{-1}$ laccase. The fluorescence reaction between *n*-(4′-hydroxyphenyl)-*N*-(4-methylquinolinyl)amine, hydrogen peroxide, and cobalt(II) was remarkably enhanced in the presence of cationic surfactant media.[376] The fluorescence output was about five times greater in the presence of trimethylstearylammonium chloride (STAC) than in its absence. This reaction was employed to determine

hydrogen peroxide in the 0–250 ng mL^{-1} concentration range.[376] Brij-35 was found to be effective in increasing the rate (roughly sixfold) of the hemin-catalyzed fluorogenic reaction between hydrogen peroxide and *N,N′*-dicyanomethyl-*o*-phenylenediamine.[377] The subsequent method for peroxide was more sensitive (by a factor of ca. 5) in the surfactant medium compared to that in aqueous solution in absence of the Brij-35.

Thiols react with 4-nitro-*N*-*n*-butyl-1,8-naphthalimide (4-NBN) to form highly fluorescent products that can be employed for the fluorimetric determination of thiols.[378] The rate of this reaction was greatly enhanced (by a factor of ca. 10^5) by the presence of cationic CTAC micelles. This increased rate was attributed to the micellar concentration of the reactants and the micellar effect on the extent of the acid–base ionization that generates the reactive thiolate anion which is the nucleophile.[378]

A very popular fluorimetric method for the determination of primary amino compounds is based on their reaction with *o*-phthalaldehyde in the presence of thiols (such as 2-mercaptoethanol) under basic conditions to form the fluorescent 1-(2′-hydroxyethylthio)-2-alkylisoindole product.[379] The isoindole product formed from many analytes is unstable owing to subsequent decomposition and oxidative reactions. The presence of different micellar and CD organized media can slow such undesired reactions involving the fluorophore.[379,380] For an overview of the effect of different CD media upon Roth's method and the fluorescence output from over 45 different aromatic organic compounds, the reader is referred to Frankewich et al.[380]

2.3.4 *Organized Assembly Effects upon Chemical Equilibrium*

Surfactant micelles and vesicles as well as CD media can shift the position of ground-state chemical equilibria. Perhaps the most important and frequent analytical application of such equilibrium shift media has been to alter the position of acid–base equilibrium.[11,12,94,101,152,381–408] Acid–base ionization constants (and other equilibrium constants) can be altered, some by several orders of magnitude, in the presence of organized assemblies compared to those observed in bulk aqueous solution (selected data presented in Table 5). A quantitative method for the evaluation of the influence of surfactant micellar media upon the protolytic equilibrium of various organic reagents has been published.[399] Micelle-induced pK_a shifts are due to "medium" (altered microenvironment) and electrostatic effects.[152] Interfacial water is known to be less polar than bulk water and is akin to an electrolyte salt solution (the ionic strength in the Stern layer of ionic surfactant micelles can be in the range 1.0–3.0 M). The degree of dissociation of the charged

Figure 3 Plots of the degree of dissociation of tetracaine as a function of pH in aqueous solution (●) and in the presence of the surfactant micelles CTAB (△), Triton X-100 (○), and SDS (▲). (Reproduced with permission from Garcia-Soto and Fernandez.[388])

aliphatic amino group of tetracaine as a function of pH in the absence and presence of surfactant-forming micelles is shown in Figure 3. As can be observed, compared to the curve in bulk aqueous solution, the presence of surfactant micelles can shift the ionization curve to either higher or lower pH values.[388] For example, while the ground-state pK_a (and excited-state pK_a) of 4-methyl-7-hydroxyflavylium cation in water is 4.4 (ca. −1.0), values of 2.25 (0.05), 3.3 (−1.2), and 6.5 (0.3), respectively, were reported in the presence of CTAB, TX-100, and SDS micellar media.[409] Hence organized media can function as pH shift reagents.

Likewise, a shift of the pK value of one unit was reported for tetracaine in the presence of egg yolk PC liposomes and as large as 1–3.5 units for 5-doxylstearic acid and 16-doxylstearic acid in PC liposomes, respectively.[400–402] Cationic surfactant media typically enhance the acid dissociation (decrease pK_a's) of organic compounds, whereas anionic surfactant media have the opposite effect (see Figure 3).

The pK_a of acids in the presence of CDs is typically larger than (or equal to) that observed in the absence of the CD, whereas the pK_a of phenolic compounds is generally smaller than (or equal to) that in the absence of the CD.[160,161] The pK_a's of seven flavonols were found to increase slightly with increases in the β-CD concentration.[323] Typically, the magnitude in the shifts of the pK values in CDs is not as great as that observed in surfactant vesicle or micellar systems.

The kinetics of the excited-state protolytic dissociation of 1- and 2-naphthols in aqueous solution, micelles, and liposomes has been examined.[347,384,406,407] Many analyte molecules, such as 2-naphthol, when excited in neutral aqueous solution, undergo spontaneous deprotonation as a result of the fact that the pK_a of the excited state can be 6–7 units lower than that of the ground state. For

[b] Refers to 4-(2-pyridylazoresorcinol).
[c] Refers to cetylpyridinium bromide (CPB).
[d] DDAB refers to didodecyldimethylammonium bromide.
[e] DMPC refers to dimyristoylphosphatidylcholine.
[f] DPB refers to dodecyldimethyl propiobetaine.
[g] Refers to the Stern–Volmer constant, K_{sv}, for the quenching of dipyridamole (DIP) by acrylamide in buffer at the indicated pH.(383)
[h] Refers to 1-(2-pyridylazo)-2-naphthol (PAN).
[i] Refers to the Stern–Volmer constant, K_{sv}, for the quenching of the indicated fluorescent molecule by quencher molecule or ion in aqueous solution or organized assembly system.
[j] Refers to 2-(*p*-aminophenyl)-3,3-dimethyl-5-cyano-3*H*-indole.
[k] Refers to 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridinio)-1-phenolate.
[l] Refers to 9-(3-pyrenyl)nonanoic acid.
[m] CMC of ethonium surfactant micelles is 2.15 mM.(397)
[n] Refers to cationic surfactant 1-ethoxycarbonylpentadecyltrimethylammonium bromide.

example, 2-naphthol has a pK_a (in water) of 9.4–9.5, but in the first excited singlet state, the pK^*_a drops to 2.8; it is a much stronger acid in its excited state.(403,404) The presence of organized media can impact both those values. In the case of benzimidazole, the $pK_{a(water)}$ is ca. 13.1, whereas the $pK^*_{a(water)}$ is 12.1.(98) However, in the presence of 0.10 M CTAB, these values are 11.6 and 11.5, respectively.(98)

As a consequence of such solute pK shifts, the use of an appropriate organized assembly system alters the pH requirements for the fluorescence assay, functioning as pH shift reagents.(404) For instance, in the

determination of ethylenediaminetetraacetate (EDTA), the optimum pH for formation of the fluorescent EDTA–Zr(IV)–Alizarin red X ternary complex is shifted toward a lower range (pH 4.5–5.5) in the presence of CTAB micelles compared to that seen (pH 5.3–6.3) in the absence of micelles.[405] The CTAB micelle medium allows the formation of the complex at more acidic conditions, which leads to an increase in the stability constant of the complex.

Likewise, the optimum pH required for the horseradish peroxidase (HRP)-catalyzed fluorogenic reaction between hydrogen peroxide and *p*-hydroxyphenylpropionic acid (HPPA) was shifted from 8.0 in aqueous solution to ca. 7.5 in aqueous solution containing CTAB micelles.[410] The lower pH requirement in the presence of CTAB leads to less deactivation of the enzyme, HRP, compared with that observed in bulk aqueous solution.

The effect of micellar and CD organized media upon the position of the keto–enol equilibria of different 1,3-dicarbonyl compounds, as well as on their pK values and reactivity, was the topic of a comprehensive study by Iglesias.[411]

Thus, in some situations, it is possible to utilize organized assembly systems as ''pH shift'' (or other ''equilibrium shift'') reagents to facilitate desired fluorogenic reactions in chemical analysis.

2.3.5 *Bulk Solvent and Microscopic Properties of Organized Assemblies*

Micellar, vesicular, and CD organized assemblies are fluid, transparent to ultraviolet light, stable, and macroscopically homogeneous. They are particularly attractive for use in analytical spectroscopy in general because they are commercially available, relatively nontoxic, and environmentally benign, and their solutions easy to prepare. Also, because of these characteristics they have been employed in numerous photochemical and photophysical investigations.[1–8,18,360,364]

In particular, the fluorescence properties of aromatic probe molecules have proved invaluable as a tool to provide information on micellar systems, such as determination of micellar parameters (CMC and N) and estimates of microscopic polarity and viscosity, water content, partitioning between water and micelle phase, permeability for quenchers, etc.[1–8,410–415] A mini review nicely summarizes the influence of the solvent medium on the energy of electronic states of organic molecules.[416] As a consequence of such medium solvatochromatic effects, fluorescence measurements often exhibit differences between fluorescence parameters (such as emission wavelength maximum, λ_{em}; excited-state lifetime, τ; quantum yield; φ; FI; etc.) obtained in an aqueous solution relative to that obtained in aqueous organized assembly solutions.

A number of different techniques have been employed to determine the apparent effective microscopic environment experienced by bound solutes in organized systems. Table 1 compares some of the properties of bulk solvents to the microscopic environmental properties experienced by solutes when bound to different organized assembly media. The term *micropolarity* typically refers to the effective polarity experienced by the solute when bound to a particular organized assembly and is a reflection of the porosity or extent of water penetration into the hydrocarbon portion of that organized medium.[417] A compilation of the effective dielectric constants in organized surfactant media is available.[30] Such results indicate that the apparent dielectric constant of the interfacial region of micelles, bilayers, and microemulsions is substantially lower than that of bulk water (Table 1). In general, the polarity of micellar interfaces decreases with increasing surfactant chain length and surfactant concentration. It decreases with temperature. It is interesting to note that the static dielectric constant of aqueous salt solutions (in the absence of any organized assembly) is considerably lower than with water alone. For example, all salts show a lowering of the dielectric constant; at 21 °C, the dielectric constant of aqueous sodium chloride solutions ranges from 73.9 (0.5 N NaCl) to 48.4 (5.0 N NaCl solution).[37] For cationic and anionic surfactant systems, the concentration of ions (counterions) in the micelle Stern layer region has been estimated to be about 3.0 M.[5,418]

For PC vesicles and multibilayer systems, a lower polarity than that of aqueous normal micelles is typically observed.[90] Microemulsion systems exhibit a polarity similar to that of aqueous micelle media. The effective polarity of the CD cavity has been reported to be equivalent to the polarity of an 80:20 (v/v) methanol–water or ethanol mixture.[65,419] The range of values for the effective polarity of CDs has been thought to be due to the fact that (i) some probe molecules might not be entirely included within the cavity of the CD, (ii) the number of included water molecules present in the complex might be dependent upon the nature of the solute, and (iii) the probes most frequently employed respond primarily to the bulk polarity of the region and their sensitivity to hydrogen-bonding interactions might be very weak.[65] More important, the polarity or microenvironment sensed by a specific probe depends on the position that the probe occupies within the CD cavity.[36]

The term *microviscosity* or *microfluidity* is typically a measure of the extent of hindrance experienced by a solubilized molecule for translational motion within a particular micelle, vesicle, or CD organized system.[417] Micellar microviscosity values are sensitive to the reporter molecule's position in the micelle aggregate. For instance, using the probe dipyrenylpropane as a reporter molecule, the microviscosity of SDS micelles

was estimated to be ca. 19 cP at 20 °C.[89] However, when diphenylpropane is used as the reporter probe molecule, a considerably smaller value for the microfluidity was obtained, namely $\eta \approx 4$ cP. Use of *N*, *N*, *N*′, *N*′-tetramethyldiaminodiphenylketoimine hydrochloride as the probe molecule yielded an estimate of 5 cP for the viscosity in SDS.[420] A value of 4.3 cP has been determined from examination of the excited-state torsional relaxation of the probe 1,1′-dihexyl-3,3,3′, 3′-tetramethylindocarbocyanine iodide.[421] Such differences in estimates of microenvironmental parameters can be due to different solubilization sites of the probe molecules, and/or reflect nonisotropic fluidity (or environmental property) in some organized assembly systems. Such influence of the size of the probe molecule upon the observed microfluidity of lipid bilayer/vesicle and bile salt systems has also been reported.[422,423] An excellent discussion of the fluidity parameters of the lipid regions of micelles and liposomes as determined by fluorescence polarization measurements is available.[422]

In most cases, the variation in the ε, η, and $E_{T(30)}$ values for a particular organized assembly system can be rationalized in terms of the different time-averaged locations for the various probe molecules employed to probe that specific system and in the appropriate choice of the probe and empirical scales employed.[71,80,240,242] It has also been pointed out that in many cases the reported values do not reflect the microenvironment of the micelle-bound probe since they were determined at surfactant concentrations <50 mM;[66] hence there are different degrees of interaction of the probes with their environments.[71] Thus, comparisons between systems should be made only if the same probe molecule was employed using the same technique for determination of the microenvironment parameter under consideration. Also, mixed micelles or organized assembly systems have different binding sites and microenvironments compared to that of their respective individual components.[423] The presence of additives can dramatically impact some of these microscopic parameters as well. For instance, the apparent microviscosity of CTAB was estimated at ~40 cP, whereas the values were 200–300 cP or ~400 cP for CTAB with added cetyl alcohol or 1-hexadecanesulfonate, respectively.[83]

The reduced fluidity of analytes in surfactant micelles has recently been utilized for analytical advantage. Strong rotational depolarization of fluorescence is typically observed for small molecules in bulk homogeneous solutions. However, when bound to organized assemblies, such small molecules experience a highly viscous, less fluid microenvironment which results in their fluorescence being partially polarized. Yan and Myrick have taken advantage of this and shown that it is possible to differentiate between different xanthene dyes on the basis of their micelle-enhanced steady-state fluorescence polarization (SSFP) even though the dyes' regular fluorescent emission spectra were almost identical.[424]

Demas et al.[425,426] have described a novel fluorescence technique which allows determination of the solvent environment around solutes, specifically, the degree of solvent (water) accessibility of a micelle-bound solute. Novaki and El Seoud[66] have reported that the effective water concentrations at the solubilization sites of different solvatochromic probes in cationic micellar media range between 22.1 and 47.8 M, depending upon the specific probe, surfactant micelle, and reference solvent mixture employed. Another report estimated water concentrations of 3.0, 54.0, and 14 M at the solubilization site of 9-anthroate in micelles of Triton X-100, SDS, and DTAC, respectively.[427]

It has been estimated that for ionic surfactant micelle systems the concentration of counterions in the micellar Stern layer is of the order of 3 M.[5,418] The refractive index for aqueous micellar solutions has been reported to be in the range 1.3–1.5, depending on the specific surfactant, its concentration, and the presence or absence of other additives.[428–431] Of course, the effects of the refractive index of the solvent system can influence some of the solution-phase photophysical properties of molecules (such as their fluorescence decay times).[430,432]

3 ORGANIZED ASSEMBLIES IN ANALYTICAL FLUORESCENCE MEASUREMENTS

A number of specific reviews on the applications of surfactants,[14,433–438] micelles,[9,14,20,433,434,438–444] microemulsions,[440,445,446] reversed micelles,[446] CDs[13,173,435–439,447–449], and related media in analytical spectroscopy have been published, each of which typically has a section dealing with fluorescence measurements in such media. Excellent overviews on the utilization of organized assemblies to facilitate luminescence analysis of environmental species have recently been published.[14,173] A review concerning the use of organized assemblies to enhance analytical chemiluminescence measurements is also available[166] (*see* **Chemiluminescence, Electrogenerated**).

3.1 Enhancement of Fluorescence Intensity in Organized Media

3.1.1 Effect of Organized Media Upon a Solute's Fluorescence Properties

Upon transfer from a bulk solvent, such as water, to an organized assembly phase, the luminescence properties (such as excitation and emission wavelengths, λ_{ex} and

λ_{em}, lifetime, τ, and emission intensity) of many solutes can be altered, sometimes dramatically. [14,18,20,409,438,439] For instance, the inclusion of organic compounds in CDs frequently leads to fluorescence enhancements and also a shift of the emission maximum toward shorter wavelengths.[438,439,450,451] Figure 4 illustrates the effects of increasing concentrations of different surfactants upon the maximum fluorescence emission wavelength of 4-cyano-4′-propoxybiphenyl.[180] With increases in surfactant concentration, the respective micelles of these surfactants form and biphenyl binds to them, resulting in an alteration (shift to shorter wavelength) of the emission wavelength due to a change in the effective microenvironment experienced by biphenyl. The polarity of the respective micelle–biphenyl binding sites is similar to that observed in bulk solvents that are less polar than water, such as DMF or ethanol.[180] The different concentration ranges over which the emission wavelength changes merely reflect the fact that these four micelle-forming surfactants have different CMC values (ranging from 6.1×10^{-5} M for NPh-EO9 to 1.2×10^{-4} M for NPh-EO30 and 8.0×10^{-3} M for SDS).[180]

Numerous other such examples are available.[452–458] Upon addition of surfactant micelles, the fluorescence wavelength observed for the Al–lumogallion complex shifts to 552 nm, compared to 584 nm in bulk aqueous solution.[453] Likewise, a 15-nm blue shift of the emission wavelength from 350 to 335 nm is observed when PS vesicles are added to aqueous buffered solutions

Figure 4 Plots of the maximum fluorescence emission wavelength, λ_{em}, of 4-cyano-4′-propoxybiphenyl as a function of increasing concentrations of the surfactants: (1) nonylphenol polyoxyethylene glycol (9–10) [NPh-EO9]; (2) nonylphenol polyoxyethylene glycol (30) [NPh-EO30]; (3) SDS; and (4) CTAB. The arrows to the right indicate the λ_{ex} maximum obtained in the bulk solvents water, dimethylformamide (DMF), and ethanol in the absence of any surfactant. The descending dotted lines indicate the CMC values for these four surfactants. (Reproduced with permission of Wiley-VCH from C. David, E. Szalai, D. Baeyens-Volant, *Ber. Bunsen-Ges. Phys. Chem.*, **86**, 710–716 (1982).)

containing cardiotoxin.[282] A blue shift of the 8-anilino-1-naphthalenesulfonate (ANS) emission maximum from 515 nm in aqueous solution to 480 nm in DMPC vesicles was reported.[133] The fluorescence emission wavelength of 4-aminophthalimide is shifted from 540 nm in water to 513 nm in 2 mM β-CD.[293] In the presence of SDS micelles, the emission maxima for 2-anilinonaphthalene-6-sulfonic acid and *N*-phenylnaphthylamine were found to be blue-shifted by 28 and 41 nm, respectively, compared to that in bulk aqueous solution.[342,343] The maximum fluorescence emission wavelength observed for the niobium(V)–lumogallion-tartaric acid complex shifted from 630 nm in aqueous solution to 610 nm in the presence of Triton X-100 micellar media.[454] For some analytes, red shifts are observed. For instance, the emission wavelength of [2-chloro-3-(2,2-dicyanoethenyl)-2-cyclopenten-1-ylidene]methylpyridinium salt shifted from 615 nm in pure water to 626 nm in an aqueous solution of Triton X-100.[46] Similar shifts were observed for other carbocyanine-type probe molecules.

More important than the shifts in emission wavelengths are the intensity enhancements observed for many fluorescent species. Many fundamental photophysical studies present data that clearly demonstrate that the fluorescence quantum yields and FI of organic molecules and inorganic metal complexes can be enhanced in the presence of ordered media in comparison to that observed in bulk solvent systems.[14,20,148,173,282,307,438,448,455–589] Some representative data is presented in Table 6. It should be cautioned that not all the results noted for a particular compound were obtained under the same standard or optimized conditions, and hence direct quantitative comparisons are not possible in such cases. However, the bottom line is that addition of surfactant and bile salt micelles, vesicle/liposomes, and/or CDs can elicit enhanced fluorescence from a range of potential analytes that in many cases can be translated into improved sensitivity in fluorescence assays for those species.

In addition, the fluorescence intensities of a number of other organic molecules were reported to be intensified, but no quantitative data were provided as to the magnitude of such enhancements. Most such reports were in the context of physical, photochemical, or binding studies rather than analytical applications. For example, the luminescence intensity of the following organic compounds was reportedly enhanced by the indicated organized media: doxorubicin (in the presence of β- or γ-CD)[285]; ANS and 2-*p*-toluidinylnaphthalene-6-sulfonate (by SDS and Triton X-100 micelles or β-CD)[38,73]; perylene (by CTAB)[60]; 2-[*p*-(dimethylamino)phenyl]-3,3-dimethyl-5-cyano-3*H*-indole (by β-CD)[65]; pyrene

Table 6 Summary of fluorescence enhancements of drugs, vitamins, dyes, and other organic substances in different organized assemblies

Compound(s)	Organized system	Enhancement factor[a]	Comment	References
Aromatic carboxylic acids	CTAB micelles	2–3[c]	[b]	458

[a] Fluorescence enhancement factor refers to the ratio of the FI of the indicated analyte molecule in the presence of the organized medium relative to that observed in a homogeneous bulk solvent under otherwise identical experimental conditions.
[b] Fluorescence enhancement attributed to protection of the analyte from collisional deactivation due to the presence of the organized assembly.
[c] Value relative to bulk water; for ionizable analytes, the magnitude of the enhancement value often depends on the concentration of the particular organized assembly system and upon the solution pH.
[d] Enhancement attributed to increased microviscosity in the lipid bilayer, which diminished competing, nonradiative processes.
[e] α-Tocopherol fluorescence enhanced in liposomes.
[f] Enhancement attributed to a shift in the position of the solute monomer–dimer–multimer equilibrium; from the multimeric or dimeric form (which is usually weakly or nonfluorescing) in the bulk solvent to its monomeric form (which is fluorescent) in the presence of the indicated organized medium.
[g] Enhancement factors are pH dependent.
[h] Value relative to that in dioxane as bulk solvent.
[i] Value relative to that in toluene as bulk solvent.
[j] Values are dependent upon the CD concentration.
[k] Refers to cetyldimethylethylammonium bromide.
[l] Increases in the fluorescence lifetime and emission intensity of the solute observed in the organized system.
[m] Values relative to that in hexane as the bulk solvent.
[n] Refers to PS.
[o] FI is increased in the vesicle system because of the more structured and ordered microenvironment.
[p] Enhancement attributed to micropolarity effect, i.e. the tryptophan moiety in the toxin, which fluoresces, experiences a less polar environment in the vesicle system, and is also less accessible to quenching from water molecules.
[q] Auramine refers to *N*, *N*, *N′*, *N′*-tetramethyldiaminodiphenylketoimine hydrochloride.
[r] Refers to DMPC vesicles.
[s] Refers to aminoacyl monomethylamide derivatives of *o*-aminobenzoic acid, where X_{aa} = Arg, Phe, Leu, and Glu.[368]
[t] Enhancement attributed to the less polar and more rigid micellar microenvironment which restricts the movement of the analyte molecule.
[u] Refers to 4′-*N,N*-dimethylamino-3-hydroxyflavone.

Table 6 (*footnote continued*)

[v] Refers to 2-(4-alkylamino-2-hydroxyphenyl)benzothiazole.
[w] Refers to *N,N*-dimethyldodecylamine-*N*-oxide.
[x] Relative to ethanol or methanol as the reference bulk solvent.
[y] Enhancement due to binding to micelle which restricts the rotational freedom of the azine molecule.
[z] Enhancement due to deaggregation of indicated solute molecules in presence of micelle or lipid systems.
[aa] Enhancement attributed to inhibition of the radiationless decay due to the greater rigidity (greater microviscosity) experienced by the organic compound when bound to the micellar aggregates.
[bb] Obtained from *Naja mossambica*.
[cc] Enhancements attributed to formation of inclusion complexes which results in a decrease in the solutes' rotational freedom and elimination of water molecules in the vicinity of the fluorescent molecules.[268,293]
[dd] Refers to 2-(*p*-aminophenyl)-3,3-dimethyl-5-cyano-3*H*-indole.
[ee] Refers to 2-(*p*-toluidinyl)naphthalene-6-sulfonate.
[ff] Enhancement due to the less polar microenvironment experienced upon binding to the indicated ordered medium.
[gg] Refers to 4-[2-(2-pyridyl)ethenyl]- and 4-[2-(4-pyridyl)ethenyl]-chalcones.
[hh] Enhancement attributed to increased medium viscosity accompanying solute binding to the SDS micelles.
[ii] Refers to 2-chloro-3-(((2,2-dicyanoethenyl)-2-cyclopenten-1-ylidene)methyl)pyridinium chloride.
[jj] Refers to egg PC vesicles.
[kk] Refers to DMPS.
[ll] Refers to DPPC.
[mm] Value depends on the temperature.
[nn] Refers to dihexadecyldimethylammonium bromide.
[oo] Refers to *N,N′*-bis(2-ethyl-1,3-dioxolane)kryptocyanine.
[pp] Refers to saturated PC.
[qq] Refers to the surfactant $C_{12}H_{25}C_6H_4SO_3Na$; CMC = 2.0 mM.[516]
[rr] Refers to 3,3-dimethyl-2-phenyl-3*H*-indole.
[ss] Refers to 2-(*p*-hydroxy)styryl-3-methylquinolizinium bromide.
[tt] Refers to (dibutylamino)stilbazolium butylsulfonate.
[uu] Refers to DTAB.
[vv] Relative to a 1 : 99 (v/v) acetone–water system.
[ww] Enhancement attributed to micellar effects upon the nonquinoid lactone–quinoid tautomeric equilibrium of the dye molecule, so that a greater portion of the molecules are in the nonaggregated, quinoidal form.
[xx] Refers to 2-[(*p*-amino)phenyl]-3,3-dimethyl-5-cyano-3*H*-indole.
[yy] Relative to methanol as the bulk solvent.
[zz] Refers to 5,10,15,20-tetra(*m*-hydroxyphenyl)chlorin.
[aaa] Refers to 4,4′-(2-pyridylmethylene)diphenol diacetate.
[bbb] Relative to 20:80 (v/v) methanol–water solution as bulk solvent system.
[ccc] Refers to 4-(*N,N*-dimethylamino)benzonitrile.
[ddd] Refers to 4-(*N,N*-diethylamino)benzonitrile.
[eee] Enhancement in micellar media reported to be due to the restriction exerted by the micelles on the formation of the nonemissive biradical state P^*.[535]

NaLS, sodium lauryl sulfate; CDEA, cetyldimethylethyltrimethylammonium bromide; TNS, 2-*p*-toluidinonaphthalene-6-sulfonate; TTCDF, 2,3,7,8-tetrachlorodibenzofuran.

(by γ-CD)[283]; 1-anilinonaphthalene-8-sulfonate (by γ-CD)[545]; carbazole alkaloid derivatives (by βCD and derivatized β-CDs)[205]; naphthalene (by β-CD and β-CD containing added sodium tetradecyl sulfate, TDSS)[207]; 1-dimethylaminonaphthalene 5-sulfonamide (by CTAB micelles and egg lecithin liposomes)[75]; diphenylpolyenes (DMPC, DPPC, and DODAC vesicles)[104]; anthracene derivatives (by CTAB, CTAC, SDS, Brij-35, and SB-12 micelles[471]; acridine orange (by SDS and other micellar systems)[70,546,547]; fluorescamine-derivatized peptides (by β-CD)[548]; 9,10-dimethylanthracene and *N*-methyldiphenylamine (by CTAC and CTAB micelles)[349]; coumarin 540A (by α- and β-CD)[549]; 7-(diethylamino) coumarin laser dyes (by γ-CD)[550]; *p*-dimethylaminochalcone (by β-CD)[103]; rhodamine 6F and oxazine 725 dyes (by SDS)[551]; some isomeric estrogens (by β-CD)[552]; eosin (by various nonionic, anionic, and cationic surfactant micelles)[553]; the tripeptide lysyltryptophyllysine (by DMPS)[134]; benzo[*a*]pyrene (by PC vesicles)[126]; hepatitis A virus peptide (by DPPC liposomes)[554]; DPH (by 1-*O*-octadecyl-2-*O*-methyl-DL-glycero-3-phosphorylcholine vesicles and Triton X-100 micelles)[555]; Oxonol VI (by dioleoylphosphatidylcholine vesicles)[307]; 9-aminoacridine and Atabrine (by lipid bilayers)[308]; rhodamine 6 Zh, rhodamine B, rhodamine 6G, Nile blue, and oxazine 1 (by various surfactant micelle media and PC liposomes)[102,136,516,556–558]; rhodamine B-labeled thyroxine (by SDS micelles)[558]; Nile red, also referred to as *Nile blue A oxazone* (by micelles and lipids/liposomes)[202,559,560]; oxonol V (by dioleoylphosphatidylcholine vesicles)[561]; 2-aminonaphthalene (by CTAB micelles)[74]; dihematoporphyrin ether or ester (by CTAB micelles)[562]; styryl derivatives of quinolizinium salts (by CTAB, SDS, and Brij-35 micelles)[519];

14 quinolizinium salts (by SDS and Brij-35 micelles)[563]; 11 *trans*-stilbene derivatives (in SDS and CTAC micelles and DPPC and dicetyl phosphate vesicles)[242]; pinacyanol (by SDS micelles)[102]; acrylodan-labeled bovine serum albumin (by SDS, CTAB, and several other cationic micellar media)[564]; amphiphilic ruthenium complex (by $C_{12}E_6$ micelles)[565]; cresyl violet (by SDS micelles)[566]; Triton X-405 (by Brij-35 micelles)[567]; pyronin Y (by SDS and CTAB micelles)[357]; trimethinethiacyanine dye (by cationic vesicles)[148]; phenolphthalein, diphenylamine, phenylfluorone, *o*-dianisidine, 2,2′-dipyridylketone azine, phenyl-2-pyridylketone hydrazone, 1,3,5-triphenyl-Δ^2-pyrazoline, and 2,3-diphenyl-hexahydro-$\Delta^{1,7}$-isoindazole (by various nonionic surfactant micelles)[530]; naphthylethanols (by β-CD)[568]; *N,N*-diethylaminoethyl (2,*N*-methylamino)benzoate (by egg PC vesicles)[515]; fluorenone (by α-CD)[317]; 1,4-diphenyl-1,3-butadiene (by γ-CD)[569]; diflunisal (by β-CD and γ-CD)[568]; 2,6-dimethylphenol and 2,4,6-trimethylphenol (by β-CD)[269]; triazinylaniline derivatives (by DMPC and DPPC vesicles)[511]; aflatoxins (by α-, β-, and γ-CD)[570]; cholestatrienol (by a mixed 1-palmitoyl-2-oleoylphosphatidyl-choline–cholesterol vesicle system)[571]; various coumarin derivatives (by β-CD)[572,573]; benzo[*a*]pyrene (by liposomes)[103]; triazinylaniline derivatives (by DMPC and DPPC vesicles)[511]; 3-hydroxy-2-naphthoic acid (by β-CD)[574]; cinalukast and montelukast (by α-CD and modified β-CD)[14]; ochratoxin A (by β-CD)[322]; 4-dimethylamino-chalcone (by TX-100 micelles)[575]; and fenoprofen (by β-CD).[576] Thus, organized media can produce an increase in FI of a wide variety of organic compounds compared with that obtained in an aqueous (or organic) medium under otherwise identical instrumental conditions. In most instances, such increased fluorescence facilitates analytical determination of those solutes due to enhanced sensitivity, as will be illustrated in a later section.[99,433,447,500,536]

For the following analytes, the presence of organized assemblies has no appreciable effect (or only a very modest enhancement) upon the FI: coumarin-6-sulfonyl chloride (in SDS or CTAB micelles)[577]; coumarin 480 (by CTAB, SDS, and Triton X-100 micelles)[578]; indole (by α-CD)[579]; uranium–*o*-hydroxyhydroquinonephthalein complex (by SDS and Tween 20 micelles)[580]; 1-amino-4-hydroxyanthraquinone, 1,5-dihydroxyanthraquinone, oxine, and 2,2′-dipyridylketone hydrazone (by various nonionic surfactant micelles)[530]; bimanes (by β-CD)[206]; fluorenone (by β-CD)[207]; testosterone enanthate, caffeine, ephedrine, chlorthalidone, dihydrochlorothiazide, and spironolactone (by SDS micelles)[531]; 8-methoxypsoralen (by β-CD)[536]; and *p*-cresol (by β-CD).[269]

The differences in the fluorescence enhancement factor observed (Table 6) for the same solute in different organized assemblies are a consequence of differences in binding interaction between that solute and the specific organized medium and the specific microenvironmental properties experienced by the bound solute. As a result, the fluorescence enhancements depend upon the specific experimental conditions (i.e. type and concentration of the organized assembly, pH, presence of other additives and cosolvents, etc.). Figure 5(a) illustrates the variation of the FI of chlorophyll *a* and *b* as a function of the concentration of Triton X-100.[518] The intensity increases with Triton X-100 concentration, reflecting the effect

Figure 5 (a) Dependence of the FI of chlorophyll *a* (A) and chlorophyll *b* (B) as a function of increasing concentration of the nonionic surfactant Triton X-100. (Reproduced with permission from Santana et al.[518]) (b) Plots of the relative FI of [2-chloro-3-(2,2-dicyanoethenyl)-2-cyclopenten-1-ylidene]–methyl pyridinium salt versus the logarithm of the surfactant SDS, CTAB, or Triton X-100 concentration. The fluorescence measurements were made at the maximum emission wavelength for each surfactant system, i.e. 626 nm in Triton X-100, 624 nm in CTAB, and 620 nm in SDS. (Reproduced with permission of Wiley-VCH from M.A. Kessler, O.S. Wolfbeis, *Ber. Bunsen-Ges. Phys. Chem.*, **93**, 927–931 (1989).[46])

of micelle formation and binding of chlorophyll to the micellar aggregates, after which the intensity levels off. Figure 5(b) illustrates the effect of the concentration of three different charge-type surfactants, nonionic Triton X-100, cationic CTAB, and anionic SDS, upon the FI of ((2-chloro-3-(2,2-dicyanoethenyl)-2-cyclopenten-1-ylidene)methyl)pyridinium salt.[46] In the case of Triton X-100 and SDS, the FI remains unaffected as the surfactant concentration is increased until the CMC is reached. At and above the CMC, an equilibrium exists between analyte molecules bound to the micellar aggregate and analyte molecules in the bulk solution. As the surfactant concentration is increased further, the number (and sometimes size) of the micelles increases such that the ratio of micellar bound to free analyte molecules becomes progressively larger until saturation is reached.[46] The greater FI in the presence of the neutral surfactant Triton X-100 compared to anionic SDS reflects the fact that the analyte binds to the former much better (probably very small binding to anionic SDS by the anionic carbocyanine solute). In the case of CTAB, the fluorescence decreased with CTAB even below CMC levels (probably owing to quenching by bromide counterions).[46] Once CTAB micelles form, the analyte is incorporated into (and protected by) the micellar aggregate with a resultant increase in its fluorescence emission. The subsequent decrease in fluorescence signal at much greater CTAB concentrations is probably due to changes in the micelle aggregate structure (change in shape from spherical to rodlike), quenching from excess CTAB, and/or quenching from impurities present in the surfactant preparation. Analyte FI versus surfactant concentration profiles similar to those shown in Figure 5(a) and (b) have been reported for many other analyte–organized media combinations.[96,99,103,108,110,187,195,271,287,525,581–586]

The fluorescence emission spectra of methyl *p*-dimethylaminobenzoate as a function of the concentration of β-CD is shown in Figure 6. The emission intensity is observed to increase with increase in the CD concentration because a greater proportion of the analyte molecules present bind to the protective CD cavity upon increasing the CD concentration.[288] In many instances, the limited water solubility of β-CD restricts one's ability to attain the maximum fluorescence signal from a particular analyte.[380]

As is evident from the data in Table 6, the magnitude of the fluorescence enhancement depends on the organized assembly system employed. For instance, the enhancement factor for the analyte auromine-O ranges from 1.4 in the presence of α-CD to 5.0 in Brij-78 micelles and 7.5 in γ-CD.[308] Nitrobenzoxadiazolyl (NBD)-labeled alkylamines exhibited greater fluorescent quantum yields in the presence of nonionic TX-100 micelles compared

Figure 6 Dependence of the fluorescence emission spectra of methyl *p*-dimethylaminobenzoate as a function of the β-CD concentration. The β-CD concentrations were (a) 0.00, (b) 0.2, (c) 0.4, (d) 0.8, (e) 1.5, (f) 2.5, (g) 3.5, (h) 4.5, (i) 6.0, and (j) 8.0 mM. (Reproduced with permission from Jiang.[288])

to that observed with α-CD or β-CD.[587] Coumarin-6-sulfonyl chloride–derivatized amino acids in a β-CD medium exhibited greater fluorescence emission than in the presence of α-CD.[584] This is presumably due to the fact that the coumarin-6-sulfonyl chloride amino acid derivatives formed stronger inclusion complexes with β-CD relative to α-CD. For the iron(III)–2-pyridinecarbaldehyde-5-nitropyridylhydrazone complex, the enhancement factors are 1.5, 2.1, 2.4, and 4.1 in the presence of micellar cetylpyridinium bromide (CPB), Triton X-100, DTAB, and hexadecyltrimethylammonium bromide, respectively.[588] In addition, even for the same type of organized assembly system, the FI can depend upon the specific chemical nature of the ordered medium.[56,95,100–103,110,418,453,529,563,583,589] For example, depending upon the specific anionic charge-type surfactant micellar system employed, the enhancement of the fluorescence signal observed for diazepam ranged from 6.2 in SDS to 2.1 in sodium α-alkenesulfonate as surfactant.[523] The FI of the aluminum(III)–lumogallion complex in the presence of nonionic surfactant micelles varies by a factor of ca. 4.5, depending on the

specific structure and nature of the nonionic surfactant employed.[95] For metal ion complexes, the metal ion–ligand concentration mole ratio can also have substantial effects on the fluorescence enhancements observed in organized assemblies. Once a given organic or metal chelate analyte is identified for analysis, the most important factor governing the observed fluorescence emission is the nature of the surfactant employed, namely, the charge type and chemical structure of the surfactant, which are the leading properties required for determining the final degree of interaction between the analyte micelles.[100,101] In general, the better the binding to the organized assembly entity, the greater will be the effect on the solute's luminescence parameters.[454] An important factor is the charge of the ordered medium relative to the actual charge of the organic analyte (or metal chelate).[100,444] For ionizable species, the pH will obviously also impact on the magnitude of binding observed and, hence, the fluorescence properties.

The degree of fluorescence enhancement is also dependent upon the amount of organic cosolvent present in the organized assembly system.[66,110,173,271,590] Figure 7 illustrates the effect of added ethanol upon the relative FI of 3,4,4′-trichlorobiphenyl (TRCB) in an aqueous nonionic polyoxyethylene(10)lauryl ether surfactant micellar solution.[107,108] The fluorescence signal in the micellar system remains essentially constant with the percentage of ethanol up to ca. 30%. At this amount of added alcohol, the micellar aggregates disintegrate and the value dramatically drops, increasing slowly again with ethanol concentrations above ca. 40%. This latter increase is practically identical to

Figure 7 Plot of the relative fluorescence of an aqueous solution of 3,4,4′-trichlorobiphenyl (TRCB) as a function of added ethanol cosolvent in the absence (dashed line) and the presence of the nonionic surfactant polyoxyethylene(10)lauryl ether. (Reproduced with permission from Hernandez Garcia et al.[108])

that obtained in an aqueous ethanol solution in the absence of surfactant.[108] Other such examples have been reported in the literature. For instance, with 1-naphthol as the fluorophore, a 50% reduction in the fluorescence enhancement factor in the presence of CD was observed if ca. 30% (v/v) methanol, ca. 20% ethanol, or ca. 10% acetonitrile was also present in the solution.[271,272] Likewise, in the presence of a 0.05 M SDS micellar system, the fluorescence enhancement observed for the diuretic amiloride was 7.4-fold, whereas in the same system with 8% (v/v) added 1-propanol, the factor was only 4.3.[528]

In the case of CDs, added organic solvents (alcohols or nitriles) can result in either an additional enhancement or diminution of an analyte's fluorescence emission. If the additive can form a 1 : 1 : 1 ternary complex (both analyte and additive included within the CD cavity), then in most instances an additional increase in the FI is observed. For example, addition of 1-butanol further enhanced the fluorescence observed from fluorene in the presence of β-CD by a factor of ca. 1.7.[303] Likewise, addition of ethanol or acetonitrile enhanced the fluorescence emission of some coumarin dyes in β- and γ-CD.[327] It was thought that the small organic solvent molecules are also included in the CD cavity along with the coumarin molecule and that such solvent molecules displace water from the cavity which would otherwise quench the coumarin fluorescence.

However, in many situations with other fluorescent species, added cosolvents lead to diminished fluorescence from analyte–CD systems.[13] This is most often the result of the fact that a rapid decrease in the solute–CD binding constant is observed with increases in the percentage of added organic cosolvents, which can be ascribed to competition between the added cosolvent molecule and the solute molecule for inclusion in the CD cavity. In addition, an increase in the percentage of organic cosolvent means that the bulk solvent system is becoming more hydrophobic and more like the microenvironment of the CD cavity; hence the solute partitions to CD to a lesser extent. The net result of such diminished binding is that less protection is afforded to the analyte molecule and its excited state is more easily deactivated via nonradiative or quenching processes, which results in diminished fluorescence.

The pH can also impact on the magnitude of any fluorescence enhancement of ionizable analytes. For example, in the case of different flavonols, the enhancement factors observed in the presence of β-CD were different under acidic conditions (for the fully protonated form) compared to that under basic conditions (for the fully deprotonated form).[289,290] In almost all cases, a greater fluorescence enhancement factor was observed for the fully deprotonated flavonol. In the case of 1-naphthol, in the presence of micellar Triton X-100,

SDS, and CTAB, the fluorescence is enhanced by a factor of 90, 66, and 20, respectively, relative to that seen in aqueous solution in the absence of surfactant.[591] Under more basic conditions, the naphthol anion emission is also enhanced in the presence of CTAB and Triton X-100, whereas in SDS its intensity decreases compared with that in water. As noted in an earlier section, the presence of organized media can alter the pK values and function as pH shift reagents.

Of course, the binding of analytes to different organized assemblies does not always result in an enhancement in the luminescence signal. In fact, for some analytes, a diminution in intensity is observed.[592] For example, the fluorescence of the following compounds (or species) reportedly decreased upon binding to the indicated ordered media relative that is observed in the bulk aqueous medium: lumichrome (by β-CD)[204]; 2-(*p*-toluidinyl)naphthalene-6-sulfonate (by CTAB)[505]; 7-ethoxycoumarin and 7-ethoxy-4-methylcoumarin (by SDS and CTAC micelles)[61]; acridine (by CTAC, DTAC or SDS)[88,593]; calcein (by bile salt, Triton X-100, and zwitterionic sulfobetaine micelles)[594]; 4,6,8(14)-triene-3-one steroids (by β- and γ-CD)[595]; coumarin (by SDS, Triton X-100, and CTAB)[596]; benzo- and methylquinolizinium salts (by CTAB micelles)[563]; fluorescein (by Triton X-100, Tween 80, and Tween 20 micelles)[492,493]; PAHs (by CPB micelles, CMC = 0.64–0.73 mM)[597]; cresyl violet (by Triton X-100 micelles)[566]; 6-propionyl-2-(dimethylamino)naphthalene, termed *Prodan* (by SDS and DTAB micelles)[598]; niobium complex of 8-hydroxyquinoline-5-sulfonic acid (HQS) (by CPB micelles)[93]; oxandrolone and methyl testosterone (by SDS micelles)[531]; fluorescein-labeled gentamycin (by SDS micelles)[558]; and uranium-*o*-hydroxyhydroquinonephthalein chelate complex (by CTAC).[580]

Most of the negative results for CTAB or CPB micelles noted above stem from the fact that the bromide counterion and/or the pyridinium ion quench the luminescence of the indicated analytes.[74,349,563,588,597] Substitution of other cationic surfactants that do not possess these moieties might result in enhanced luminescence from some of these compounds/complexes. In addition, some organic molecules exhibit weak or no luminescence in organic solvents. Thus, transfer of such compounds from bulk water to an organized assembly phase (which is relatively less polar) results in decreased fluorescence. As an example, the fluorescence of acridine in micellar CTAC, DTAC, and SDS is only 8.0, 10.0, and 29%, respectively, relative to that observed in bulk water.[593] This stems from the fact that acridine fluoresces in water but not in organic solvents. Thus, transfer from the bulk aqueous phase to the less polar microenvironment of the micellar systems results in diminished fluorescence. Obviously, in such situations the use of aqueous-based organized assemblies would not prove advantageous unless one wanted to reduce background luminescence from such species.

3.1.2 *Mechanism of Fluorescence Enhancements in Organized Assemblies*

As illustrated by the data in Table 6, a variety of organic molecules (and also metal complexes) exhibit enhanced fluorescence upon binding to surfactant micellar or vesicle/liposome aggregates or CD molecules. Upon such incorporation, a number of potential mechanisms/factors are thought to be responsible for intensified luminescence, all of which are due to increases in the rate of the radiative process relative to the various competing nonradiative processes. These factors include shielding of the analyte species from quenching by bulk water, increased local viscosity in the binding site with concomitant reduction by oxygen quenching, reduced accessibility to solvent-borne quenchers and, perhaps, reduced quenching (rates) due to the more rigid local microenvironment of the particular organized assembly. As a consequence, the fluorescence quantum yield (and singlet excited-state lifetime) of the analyte fluorophore is often greater when it is ''bound'' to an organized assembly system relative to that observed in aqueous solution.[95,454,590,599–602]

In particular, isolation of analyte molecules which contain hydrogen-bonding moieties from water or other protic solvents possessing O–H or N–H bonds eliminates quenching from those solvent molecules and gives rise to enhanced fluorescence quantum yields (and intensity).[317,380,522,601,603] Thus, binding of such analytes possessing amino or hydroxyl moieties to organized assemblies would be expected to offer the prospects of enhanced fluorescence. In addition, it was reported that enhanced fluorescence in the presence of surfactant micelles is expected for organic analytes with nonrigid structures and/or that possess several phenyl groups in close proximity.[530] For acyclic azine molecules, transfer from a bulk solvent to a host micelle is thought to limit the rotational freedom of the azine molecule, leading to greater fluorescence efficiency.[494] In some instances, particularly in the case of metal chelate complexes, a portion of the intensified fluorescence can result from an increase in the molar absorptivity of that complex in the organized medium relative to that in a bulk solvent.[381,491,527] In the case of some metal complex species, enhanced intermolecular (or intramolecular) energy transfer efficiency also contributes to the intensified fluorescence observed in such systems.[275,590,604]

Additionally, the presence of organized species eliminates (or minimizes) alternative structures (dimers, aggregates, acid–base forms, etc., which have different

fluorescent and dynamic properties) for the analyte.[35] For some analytes, particularly dyes and some drug molecules, the addition of organized media causes increases in fluorescence as a consequence of their ability to alter the degree of aggregation of the analyte molecules.[100,501,516,553,556,605–613] Typically, the aggregated (dimer, tetramer, and multimer) forms of organic species exhibit weak or no fluorescence; hence deaggregation of the multimeric form due to the presence of the organized media and binding of the monomeric form (which exhibits greater fluorescence efficiency) leads to intensified luminescence.

For instance, the dimerization constants for the dyes MB, acridine orange, MO, and rhodamine R6G in water were reported as ca. 2300, 5200, 9200, and 5600 M^{-1}, respectively.[606,614] ''Dipole–dipole interactions within the resonating dimeric structure and/or a twisted molecular structure in the dimeric molecule can result in significant fluorescence quenching.''[547] The presence of appropriate organized media (i.e. surfactant present well above the CMC) can shift the monomer $\overleftarrow{\rightarrow}$ dimer equilibrium to the left with resultant enhanced fluorescence from the monomeric form of the dye.[547] The addition of Triton X-100 to an aqueous solution of rhodamine 6G prevents such dye aggregation, which permitted development of the first continuous-wave laser.[607] The addition of CD to relatively concentrated rhodamine-containing aqueous solutions also resulted in enhanced fluorescence (due to a shift in the dimer $\overleftarrow{\rightarrow}$ monomer equilibrium).[605] However, if CDs were added to less concentrated rhodamine solutions, then the fluorescence due to the rhodamine was somewhat quenched.

CDs were also utilized to control the aggregation equilibria and state of the dyes oxazine 1 perchlorate and oxazine 170 perchlorate.[610] Also, in water, cyanine dyes slowly form dimers and H aggregates such that the fluorescence of the monomer decreases. However, in the presence of SDS micelles, no dye aggregation occurs and only monomer fluorescence is observed.[39] Likewise, Triton X-100 or CTAB micelles solubilize chlorophyll in its monomer form, whereas in water, chlorophyll aggregates to different extents.[615]

3.2 Utilization of Organized Assemblies to Improve Fluorescence Methods for Inorganic and Organic Analytes

In general, new limits of sensitivity, and often improved selectivity, can be achieved in fluorimetric methods by analytically exploiting the unique properties offered by organized assembly systems. The use of micellar, vesicle, and CD media to enhance the FI of analyte molecules (species) has led to the development of fluorimetric methods that exhibit improved sensitivity [96,99–106,113,205–207,229,307,395,405,454,465,470,500,532,581,599,616–627] and also aids in the solubilization of the organic analyte or metal chelate,[107,196,518,599,628,629] eliminating the need to use organic solvents.[187,449,630,631] Other advantages reported include better selectivity,[307,405,532,599,616,619,622,632] wider calibration range (linear dynamic range),[589,599] greater accuracy and reproducibility,[599] greater flexibility in the choice of optimum pH[619,629] and method convenience,[518,599] greater stability of the luminescent species,[581,590] and, in some cases, eliminating the need for a prior extraction, cleanup, and/or chromatographic separation step.[518,583,624,633,634] Specific examples of the utilization of organized assemblies to improve the analytical performance of fluorescence methods for a variety of organic and inorganic analytes are outlined in the following sections.

3.2.1 Determination of Organic Analytes

Various types of organized assembly systems have been employed to enhance or improve fluorimetric methods for the determination of organic compounds.[14,173,635–677] Table 7 summarizes the conditions, analytical parameters and benefits derived from use of different organized media for the improvement of fluorimetric assays for some selected organic analytes. In most instances, the primary benefit of the organized medium is enhanced sensitivity. For instance, analytical fluorescence calibration data were determined for 13 PAHs in the presence of Brij-35 micelles.[222] Detection limits ranged from 0.005 ng mL^{-1} for chrysene to 0.2 ng mL^{-1} for naphthalene. The sensitivity and selectivity of PAH determinations in this medium are better than those obtained in methanol. The Brij-35 modified fluorescence method was evaluated for the determination of pyrene, benzo[*a*]pyrene, and benzo[*ghi*]perylene in particulate air samples.[222] A method for the resolution of multicomponent PAHs in micellar media via use of linear variable angle fluorescence and chemometric techniques has been reported.[481]

Derivative synchronous fluorescence spectrometry using polyoxyethylene(10)lauryl ether ($C_{12}E_{10}$) micelles was employed to determine simultaneously 3,3′, 4, 4′-tetrachlorobiphenyl (TTCB) and 2,3,7,8-tetrachlorodibenzofuran (TTCDF), with detection limits of 5.3 and 1.3–2.7 ng mL^{-1}, respectively.[639] The presence of $C_{12}E_{10}$ enhanced the FI of TTCB and TTCDF by factors of ca. 11 and 40, respectively, compared to that observed in an aqueous 2% (v/v) ethanol solution. Likewise, a simultaneous synchronous fluorimetric method for determination of benzo[*a*]pyrene and perylene in Triton X-100 micelles was developed, with detection limits of 0.27 and 0.30 ng mL^{-1}, respectively.[640] Binary mixtures of dibenz[*a*, *c*]anthracene and coronene were determined

Table 7 Summary of experimental and analytical parameters for the determination of organic analytes in the presence of different organized assembly media

Analyte	System conditions	Analytical parameters[a]	Comments	References
Stilbestrol	Triton X-100, pH 8.80–10.20	$\lambda_{ex} = 318$ nm, $\lambda_{em} = 415$ nm, LDR = 0.0–3.0 μg mL^{-1}, $D_L = 0.03$ μg mL^{-1}	TX-100 enhanced FI by factor of 9.0 and eliminated solubility problems	599
Fenproporex[b]	SDS, 20 °C	$\lambda_{ex} = 260$ nm, $\lambda_{em} = 560$ nm, $D_L = 0.8$ ppm	SDS or other anionic micelles enhanced FI by factors of 1.6–2.7	96
Procaine	β-CD	$\lambda_{ex} = 293$ nm, $\lambda_{em} = 330$ nm, LDR = 10–680 ng mL^{-1}, $D_L = 2.5$ ng mL^{-1}	β-CD enhanced FI by factor of ca. 12	498
Chlorophyll *a*	Triton X-100	$\lambda_{ex} = 431$ nm, $\lambda_{em} = 673$ nm LDR = 0–100 ng mL^{-1}, $D_L = 0.04$ ng mL^{-1}	TX-100 enhanced FI by factor of ca. 2000; no prior separation step required	518
Chlorophyll *b*	Triton X-100	$\lambda_{ex} = 462$ nm, $\lambda_{em} = 654$ nm $D_L = 0.09$ ng mL^{-1}	TX-100 enhanced FI by factor of ca. 3000	518
Indole-4-carboxylic acid	CTAB, pH 13	Synchronous maximum $\lambda^{\circ}_{s,em} = 288$ nm, $\Delta\lambda = 100$ nm, LDR = 0–350 ppb, $D_L = 1.0$ ppb	CTAB enhanced FI by factor of ca. 341	307
Propoxur[c]	CTAB	$\lambda_{ex} = 270$ nm, $\lambda_{ex} = 295$ nm, LDR = 0–4.8×10^{-6} M, $D_L = 5 \times 10^{-8}$ M	CTAB enhanced FI 1.8-fold	106
Carbendazim[d]	CTAB, 0.10 M NaOH	$\lambda_{ex} = 306$ nm, $\lambda_{ex} = 327$ nm, $D_L = 1.3 \times 10^{-8}$ M	CTAB enhanced FI by factor of 11.6	99
Carbaryl[e]	Nemol K1030[f]	$\lambda_{ex} = 336$ nm, $\lambda_{ex} = 450$ nm, $D_L = 1.4$ ng mL^{-1}	Nonionic Nemol micelles enhanced FI ca. 1.7-fold[g]	583
TTCB	POLE[h]	$\lambda_{ex} = 264$ nm, $\lambda_{ex} = 330$ nm, LDR = 0.5–10 ng mL^{-1}, $D_L = 1.4$ ng mL^{-1}	POLE micelles enhanced FI by factor of 6.8	107
TRCB	POLE[h]	$\lambda_{ex} = 260$ nm, $\lambda_{ex} = 328$ nm, LDR = 1.0–50.0 ng mL^{-1}, $D_L = 4.9$ ng mL^{-1}	POLE micelles enhanced FI by factor of 6.6	108
2-Naphthol	SDS	$\lambda_{ex} = 322$ nm, $\lambda_{em} = 355$ nm, LDR = 0.00–0.9 ppm, $D_L = 0.015$ ppm	SDS micelles enhanced FI by factor of 1.6	490
Kinetin[i]	SDS, pH 1.4–2.4	$\lambda_{ex} = 325$ nm, $\lambda_{em} = 500$ nm, LDR = 0.21–4000 ng mL^{-1}, $D_L = 0.21$ ng mL^{-1}	SDS micelles enhanced FI by factor of 9.5	589
Piroxicam[j]	β-CD, pH 3.5	$\lambda_{ex} = 320$ nm, $\lambda_{ex} = 440$–450 nm, LDR = 0.02–1.0 μg mL^{-1}, $D_L = 0.02$ μg mL^{-1}	β-CD enhanced FI by factor of ca. 9.4	395
Nalidixic[k]	γ-CD	$\lambda_{ex} = 314$ nm, $\lambda_{ex} = 357$ nm, LDR = 0.1–2.0 μg mL^{-1}, $D_L = 0.038$ μg mL^{-1}	γ-CD enhanced FI ca. two fold	582
7-Hydroxymethyl nalidixic acid	γ-CD, pH 2.0	$\lambda_{ex} = 258$ nm, $\lambda_{em} = 363$ nm, LDR = 0.10–4.00 ppm, $D_L = 0.02$ μg mL^{-1}	γ-CD enhanced FI by factor of ca. 2.0	635
Quercetin	Ethonium dichloride micelles[l]	$\lambda_{ex} = 436$ nm, $\lambda_{em} = 540$ nm, $D_L = 5 \times 10^{-6}$ M	Micellar medium enhanced FI by factor of 1.5	397
Anthracene and derivatives	SDS and γ-CD, pH 9.3	$\lambda_{ex} = 325$ nm, absolute detection limits estimated at subfemtogram levels	Micelles and CDs enhanced solubility; detection following capillary electrophoresis	636
Diazepam	SDS, 0.5 M H_2SO_4	$\lambda_{em} = 500$ nm, $D_L = 0.04$ ppm	SDS enhanced FI by factor of 5.0	620
Piroxicam	β-CD, pH 3.5			

(*continued overleaf*)

Table 7 (*continued*)

Analyte	System conditions	Analytical parameters[a]	Comments	References
Diuretics (7)	SDS, pH 3.0	$\lambda_{ex} = 270$ nm, $\lambda_{em} = 430$ nm, D_L range from 1.4 ng mL^{-1} (for bumetanide) to 54 ng mL^{-1} (for piretanide)	Fluorescence detection using SDS micellar mobile phase in HPLC separation	528
Methyl paraben[m]	α-CD, pH 4.5	$\lambda_{ex} = 259$ nm, $\lambda_{em} = 334$ nm, LDR = 0.04–3.0 ppm, $D_L = 11$ ng mL^{-1}	α-CD enhanced FI by factor of 12	532
Trovafloxacin	SDS, pH 5.5	$\lambda_{ex} = 270$ nm, $\lambda_{em} = 410$ nm	Method about 10x more sensitive in SDS medium as compared to water	553
Moxifloxacin	SDS, pH 4.0	$\lambda_{ex} = 294$ nm, $\lambda_{em} = 503$ nm	SDS enhanced FI by factor of 2.1 and minimized background signals from biological fluids	585
Trazodone	SDS, pH 7.0	$\lambda_{ex} = 326$ nm, $\lambda_{em} = 435$ nm, DL = 1.3 nM	SDS enhanced FI by factor of ~2	554
Danofloxacin(D) and Mabrofloxacin (M)	SDS, pH 3.0	$\lambda_{ex} = 300$ nm, $\lambda_{em} = 446$ nm, DL = 0.5 ng mL^{-1} (D), DL = 5.0 ng mL^{-1} (M)	HPLC with micelle as mobile phase	555
11-Methyl benzopheno-thiazine	β-CD	DL = 1 ng mL^{-1}	–	540
Bromodiolone	β-CD CTAB	$\lambda_{ex} = 310$ nm, $\lambda_{em} = 392$ nm, DL = 23 ng mL^{-1} (β-CD), DL = 37 ng mL^{-1} (CTAB)	β-CD and CTAB enhanced quantum yields by factor of 10	544
Histamine (as its fluorescamine derivative)	Brij-700 or SDS (pH 10.0) or CTAC (pH 7.0)	$\lambda_{ex} = 380$ nm, $\lambda_{em} = 460$ nm, DL = 0.5–33 ng mL^{-1} (depends on surfactant)	Micellar media enhanced derivative stability and sensitivity of method	556
Curcumin	Mixed micelle of CTAB and sodium dodecylsulfate	$\lambda_{ex} = 423$ nm, $\lambda_{em} = 492$ nm, DL = 0.017 ng mL^{-1}	Mixed micelles enhanced the FI	557

[a] LDR refers to linear dynamic range and D_L is the detection limit.
[b] Refers to (±)-3-(α-methylphenethylamino)propionitrile.
[c] Refers to 2-(methylethoxy)phenylmethyl carbamate.
[d] Refers to methylbenzimidazol-2-yl carbamate.
[e] Refers to 1-naphthyl *N*-methylcarbamate.
[f] Refers to nonionic surfactant nonylphenol ethylene oxide (11.7); CMC = 2.0×10^{-4} M.[107,108]
[g] Carbaryl in this basic micellar medium was instantaneously hydrolyzed to 1-naphthol, with Nemon 1030 having an effect comparable to that previously reported for an aqueous 10% (v/v) ethanol solution.
[h] Refers to polyoxyethylene(10)lauryl ether, $C_{12}E_{10}$.
[i] Refers to N^6-furfuryladenine.
[j] Refers to 4-hydroxy-2-methyl-*N*-2-pyridinyl-2*H*-1,2-benzothiazine-3-carboxamide 1,1-dioxide.
[k] Refers to 1-ethyl-1,4-dihydro-7-methyl-4-oxy-1,8-naphthyridine-3-carboxylic acid.
[l] Refers to ethylene-1,2-bis(*N*,*N*-dimethyl)carbodecoxymethyl dichloride.[626]
[m] Refers to 4-hydroxybenzoic acid methyl ester.
TTCB, 3,3′,4,4′-Tetrachlorobiphenyl.

in CTAB micelles by synchronous fluorescence spectrometry, with detection limits of 0.20 and 0.22 ng mL^{-1}, respectively.[474] The simultaneous determination of chrysene, perylene, and coronene was also reported, with detection limits of ca. 0.14 ng mL^{-1} for each of these PAHs. Constant-energy synchronous luminescence spectrometry (CESLS) in conjunction with SDS micelles allowed for the simultaneous identification and determination of benzo[a]pyrene, perylene, and pyrene in a mixture.[641] The presence of the micelles obviated the need to use an organic solvent and greatly enhanced the fluorescence signals, allowing detection of these PAHs in the low nanogram per milliliter levels (limits of detection ranged from 0.34 to 0.70 ng mL^{-1}).[641]

The utilization of micellar benzyldimethylhexadecylammonium chloride allowed for the determination of indole-4-carboxylic acid with a detection limit of 1.0 ng mL^{-1}.[307] CDs were employed to enhance the fluorescence of the pesticides bendiocarb and promecarb and detection limits of 0.57 and 0.091 μg mL^{-1}, respectively, were achieved.[539] The fat-soluble vitamins; A and E, can be easily solubilized in aqueous micellar solutions,

which allowed their fluorimetric quantification in milk samples[586] with detection limits of 54.0 and 55.2 ng L^{-1}, respectively, reported with Brij-35 as the micelle.

HRP-catalyzed fluorogenic reactions involving hydrogen peroxide with substrates such as HPPA has frequently been utilized in clinical and biochemical assays. In the conduct of such assays, a sequential approach or compromise of conditions is required since the enzyme activity, reaction rate, and product FI are not at maximum at the same pH values.[630] However, if the reaction is conducted in the presence of cationic surfactants, such as CTAB or CTAC, this difficulty can be overcome, as the reaction rate is 2.4–2.6 times greater than that in an aqueous solution. A CTAB micellar modified FIA method for the determination of HRP was developed with a linear dynamic range of 0.029–290 mg L^{-1} HRP ($\lambda_{ex} = 300$ nm, $\lambda_{em} = 405$ nm).[630] The micellar rate and pH effects on this reaction sequence should also be applicable for the enhancement of the fluorimetric determination of hydrogen peroxide.

The FI of an adduct of arginine with 2,3-naphthalenedicarbaldehyde ($\lambda_{ex} = 462$ nm, $\lambda_{em} = 520$ nm) in a weakly alkaline solution was enhanced ca. 12-fold by the addition of β-CD.[642] The reaction is highly specific for arginine, so no prior separation step is required in the procedure.

HRP catalyzes the reaction of acetaminophen and hydrogen peroxide with the formation of several unknown fluorescent products. The addition of Triton X-100 results in a fivefold increase in the observed fluorescence from this system.[643] This system is thought to be amenable to coupling to other reaction systems for the determination of substrates (or enzymatic activity). As an example, a linear calibration curve was obtained for glucose in the presence of the above system and glucose oxidase.

Since aqueous (or mixed aqueous–organic) solutions of organized assemblies have been utilized as chromatographic mobile phases or electrophoretic run buffers (*see* **Capillary Electrophoresis**; **Micellar Electrokinetic Chromatography**), their benefits with respect to fluorescence detection can sometimes be achieved with these separation methods.[318,449,463,482,548,644–647] The utilization of aqueous solutions of SDS as the mobile phase facilitated the separation and direct synchronous fluorescence detection of PAHs.[645] It was noted that the micellar matrix produced an enhancement effect on the fluorescent signals. In some instances, detection limits were poorer, owing to the presence of large background signals due to the organized assemblies.[648] For instance, the detection limits for PAHs separated by capillary zone electrophoresis (CZE) using 80:20 (v/v) water–DMF containing NaDC micelles in the run buffer were not as good as that achieved using CDs in the run buffer.[646] With CDs in the CZE run buffer, significant increases in the measured FI for 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde (CBQCA)-tagged peptides were observed.[548] For instance, the relative FI of CBQCA–Des-Asp^1-angiotensin increased by almost a factor of 10.0 in the presence of 20 mM β-CD. The presence of α-CD also enhanced the fluorescence observed from the CBQCA derivatives of smaller peptides.[548] The HPLC detection of some PAHs was enhanced via the use of SDS micelles in the chromatographic mobile phase with fluorescence detection.[482]

Several articles review the enhanced fluorescence effects observed for dansylated amino acids due to the micellar mobile phases utilized for their HPLC separation,[14,463] as well as enhancements in the detection of environmental species separated by HPLC (or CE) that utilized micelles (or CDs) in the mobile phase (or run buffer).[14,449] A reversed phase HPLC method utilizing CDs in the mobile phase to enhance fluorescence detection was employed to determine aflatoxins in food and agricultural products.[649] Capillary electrophoresis utilizing a mixed β-CD/sodium deoxycholate run buffer system was found to resolve the optical isomers of D/L-serine (as their naphthalene-2,3-dicarboxaldehyde (NDA) derivatives) with laser-induced fluorescence as a means of detection (limit of detection was 3.0×10^{-8} M).[650] Alanine, glutamate, and γ-aminobutyric acid were also determined using fluorescence detection following their CE separation with a mixed micellar (SDS and sodium cholate) run buffer (detection limits in the range of 11–40 nM).[647] In addition, catecholamines and amino acids (derivatized with 4-chloro-7-nitro-2,1,3-benzoxadiazole, NBD) were separated and determined by CE via use of SDS micelles in the run buffer. The SDS served to improve the fluorescence of the NBD-labeled catecholamines.[456] The CE analysis of the mycotoxin zearalenone with CD enhanced fluorescence (limit of quantitation = 5 ng g^{-1} for maize sample) has been reported.[538]

The effect of SDS on the fluorescence observed from histone–ANS complexes has been reported.[651] The enhancement of ANS fluorescence caused by different groups of histones in the presence of SDS is roughly the same. This allowed the development of an ANS staining method for histones that is rapid, economical and simpler than the existing method for such staining of histones separated via sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE).

Enhanced fluorescence due to the presence of organized assemblies can also sometimes be employed to determine the concentration of that organized component. For example, a very sensitive fluorescence assay for phospholipid vesicles using DPH has been reported.[486,555] The FI of DPH is proportional to the phospholipid concentration, with a detection limit of

0.70 nmol reported.[486] This optimized method compared favorably with the classical, conventional methods for analysis of such vesicle systems in terms of sensitivity, accuracy, and convenience.

An HPLC method in which the fluorescence enhancement of probe molecules was utilized as the detection mode has been reported for the determination of CDs.[271,652,653] Addition of the fluorescent probe molecule to the mobile phase results in an *in situ* complexation (with resultant enhanced FI), making the use of a postcolumn reaction detection system unnecessary. With 1-naphthol as the probe molecule in the mobile phase, a detection limit of 90 pmol was reported for β-CD.[271] Use of 2-*p*-toluidinonaphthalene-6-sulfonate (TNS) as the probe molecule resulted in HPLC mass detection limits of 3.7, 0.050, and 0.14 μg for α-, β-, and γ-CD, respectively.[653] Derivatives of β-CD can be determined in an analogous manner. In similar fashion, TNS or ANS was utilized in the run buffer to enhance the fluorescence detection of nonabsorbing analytes (anionic surfactants such as SDS) in CZE and micellar enhanced/electrokinetic capillary chromatography (MECC or MEKC).[471,495] Detection limits of 0.1–0.4 mM SDS were reported, although the reproducibility was relatively poor. Also, any analyte that partitions into the micelle (present as part of the run buffer) will displace some of the added fluorescent probe molecule with a concomitant decrease in the fluorescence signal, which allows indirect detection of nonabsorbing solutes in MECC.[495] For instance, using ANS as the probe in conjunction with SDS in the run buffer allowed indirect fluorescence detection of the analytes phenol, 3,5-dimethylphenol, and naphthalene. In addition, a flow-injection titration method has recently been reported for determination of surfactants (SDS, SB-12 (*N*-dodecyl-*N,N*-dimethyl-3-ammonio-1-propanesulfonate), Triton X-100, CTAB) based upon the enhanced fluorescence observed for TNS in their presence.[653]

There are some reports concerning the use of dipping or spray reagents containing organized surfactant assemblies to enhance fluorescence detection of organic analytes following their separation by thin-layer chromatography (TLC). For example, the use of Triton X-100 dissolved in chloroform or benzene as a spray reagent enhanced the fluorescence signal of the analyte ethoxyquin by a factor of >200![654] After application, the organic solvent was evaporated, leaving the pure, viscous Triton X-100 on the silica gel TLC sheet, which resulted in the enhanced emission signal. Likewise, detection of 7-fluoro-2,1,3-benzoxadiazole-4-sulfonate (SBD) derivatized gluthathione was improved by a factor of ca. 2.0 via the use of organized assemblies in a fluorescent enhancer dipping reagent following separation via high-performance TLC on silica gel.[655] For this analyte, the fluorescence enhancement ratios obtained were 1.80, 1.85, 1.86, and 2.16 for 40% (v/v) Triton X-100 in toluene and 20 mM aqueous solutions of α-, γ-, and β-CD, respectively.[655] The detection limit achieved was 17 pg of gluthathione per spot.[656] A fiber-optic remote sensor for *in situ* fluorimetric quantification in TLC has also been reported.[657] The fluorescence signal was again enhanced by dipping the silica gel plates in a mixture of Triton X-100 and chloroform. Detection limits of 5.3 and 6.4 μM were reported for the analytes acepromazine and propiomazine, respectively.[657] Significant enhancements in fluorescence for dansylated amino acids and aromatic hydrocarbons were observed on silica gel and alumina TLC plates when using CTAC or NaC micellar or β-CD spray reagents.[658]

Some of the same surfactant micelle systems (nonionic, zwitterionic) that can be employed to enhance the FI from organic analytes can also be utilized above their cloud point (CP) for extractive preconcentration (*see* **Waste Extraction Procedures**; **Cyanogen Chloride and Cyanogen Bromide Analysis in Drinking Water**). Although nonionic surfactants dissolve in aqueous solution to form micellar aggregates, above a temperature referred to as that surfactant's CP, which is characteristic of the surfactant employed and the conditions, the surfactant phase separates from the bulk aqueous phase akin to a conventional liquid–liquid extraction process[94] (for a review, see Hinze et al.[659]). Thus, via the use of appropriate surfactants and conditions, it is possible to combine this CP extraction with fluorescence detection to achieve high concentration factors (from the CP extraction step) and also fluorescence enhancements due to the presence of the surfactant-rich aggregate phase, both of which serve to improve analyte detectability. As examples of this technology, the nonionic surfactant Genapol X 80 was employed in the CP extraction and fluorescence detection of the pesticides napropamide and thiabendazole from water and soil samples.[660] The fluorescence enhancement factors obtained in the surfactant-rich phase were 1.2–2.0 for these two pesticides. Detection limits below 0.2 μg L^{-1} were achieved with recovery rates of up to 95%. In addition, the acid-induced CP extraction using SDS served as a preconcentraion step prior to the fluorimetric determination of a number of PAHs.[661]

The presence of micellar media can often enhance the photostability of organic molecules. For instance, while irradiation of a cyanine dye in aqueous solution with a 450 W Xe lamp through a 400 nm cut-off filter resulted in a complete depletion of the dye within 30 min, no fading whatsoever was detected after 24-h irradiation in the presence of an SDS micellar solution.[39] Likewise, rhodamine 6G was found to be much more stable in SDS micellar media than in bulk methanol or ethanol

when submitted to near-ultraviolet/visible (UV/VIS) illumination from a continuous xenon arc lamp. This is a consequence of the fact that the photodegradation reaction(s) is inhibited in the presence of micellar media.

Pyridoxal is oxidized in the presence of cyanide ion to form 4-pyridoxolactone as the fluorescent product. The use of cationic CTAB resulted in an enhancement of both the reaction kinetics (by a factor of ca. 2) and also the quantum yield of the product.[662] The limit of detection of pyridoxal using the micellar-enhanced fluorescent FIA approach was 0.17 ng, which is three times lower than that achieved in an aqueous solution in the absence of surfactant.

Micellar media have also been employed to enhance some fluorescence immunoassay techniques for determination of biological/clinical molecules. Fluorescent dyes are typically employed to label analyte molecules in ligand binding assays. The assay requires that there be a fairly large difference in the fluorescence properties of the bound compared with the free labeled analyte. Halfman et al.[558] reported that SDS micelles quenched the emission of free fluorescein-labeled gentamycin without impacting the emission intensity of labeled gentamycin bound to gentamycin antibody, thus fulfilling the requirement for a large fluorescence difference between the bound and free labeled species. The micellar quenching effect thus allowed the development of a convenient homogeneous fluorescence immunoassay for gentamycin based only on FI measurements. Guidelines for the design of similar assays for other analytes and the charge-type surfactant micelles that would be required were also discussed. More recently, specially derivatized CDs have been developed that allow for the quenchofluorimetric determination of organic species, including enantiomeric compositions.[162–165,663,664] For instance, a β-CD modified to contain the dansyl fluorophore was synthesized and shown to serve as an enantioselective fluorescent sensor for amino acids. In the absence of enantiomeric analytes, the dansyl group, although chemically bound the CD, is included in the CD cavity and exhibits intense fluorescence. In the presence of an analyte, the analyte can displace the dansyl group, which when in contact with bulk solvent exhibits much diminished fluorescence. The decrease in dansyl fluorescence is proportional to the analyte concentration. Such approach has been employed as a means of sensing amino acids as well as endocrine-disrupting chemicals. Other fluorescent moieties have been appended to cyclodextrins for application as sensors (*see* **Fluorescence-based Biosensors**; **Biosensor Design and Fabrication**) for other analyte groups.

The quenching of fluorescence from acridine orange sensitized rhodamine 6G (or B) system in sodium dedecylbenzenesulfonate micelles upon the addition of analytes (such as erythromycin and vitamin B_{12}) has been employed to quantitate those analytes.[637,638]

In closing this section, it should be noted that more information and examples concerning the use of CDs in analytical fluorimetry and diagnostics can be found in a book chapter[439] and a recent review article.[173] In addition, a review by McGown et al.[665] focuses on luminescence measurements in bile salt surfactant systems.

3.2.2 *Photochemically Induced Fluorescence (PIF) Detection*

For weakly fluorescent and nonfluorescent analytes, derivatization to convert the analyte into a more detectable product (i.e. better fluorescing) constitutes a means of enhancing that analyte's detectability. In addition to chemical reactions, an alternative approach is to use a photochemical reaction.[14,666,667] In this case, intense UV/vis radiation converts nonfluorescent or weakly fluorescent analytes of interest into highly fluorescent products. Such a PIF approach has been employed as a postcolumn derivatization technique for detection in chromatographic systems.[449,668]

A flow-injection fluorimetric method for determination of vitamin K_1 based on a photochemical reaction in the presence of Triton X-100 micelles has been reported.[217,669] As previously noted, the primary function of the micellar media was to enhance the stability and solubility of different reactive species formed during the photochemical reaction. This method permits the determination of vitamin K_1 in the 10^{-6}–10^{-4} M concentration range. The anionic surfactant SDS was employed in the HPCL-PIF determination of K vitamins.[631] A FIA-PIF method for the determination of menadione in the presence of SDS with a detection limit of 0.18 mg mL^{-1} has been developed by Perez-Ruiz.[669] The determination of phylloquinone in fruits and vegetables by FIA with SDS micelle–enhanced PIF (detection limit 0.05 μg mL^{-1}) has been reported.[541]

A rapid micellar-enhanced PIF-FIA method for the determination of nonfluorescent sulfonylurea herbicides in water has been developed.[670] In this application, the primary purpose of incorporation of surfactant micellar SDS or CTAC in the carrier stream was to improve the solubility of the herbicides in an aqueous medium. In addition, the photoinduced fluorescence signals were greater by a factor of 1.1–4.1 for the four herbicides examined in the presence of the micelles compared with those in aqueous solution in the absence of surfactant micelles. Detection limits of 0.2–0.5, 0.1–0.2, 0.2–0.8, and 1.0–6.0 ng mL^{-1} were reported for the herbicides chlorsulfuron, methsulfuron-Me, 3-rimsulfuron, and sulfometuron-Me, respectively.[670,671] In similar fashion, a photochemical–spectrofluorimetric method

for determination of two pyrethroid insecticides and four phenylurea herbicides using an anionic and/or cationic surfactant micellar medium and CDs has been reported.[672–674] Likewise, such micellar-enhanced photochemically induced fluorescence approaches have been employed for the determination of other herbicides (e.g. mecoprop, chlorphenoxyacid, phenylurea residues, etc.) using time-resolved and/or flow-injection PIF techniques[449,667,675,676] (*see* **Phenyl- and Sulfonylurea Herbicides: Single Class, Multiresidue Analysis of**).

Upon irradiation, mazindol, an anorectic agent, forms a photoproduct whose fluorescence is much greater than that of maxindol itself. Irradiation of mazindol solutions in the presence of micellar SDS provokes a further enhancement in their fluorescence and the maximum FI is reached faster than in the absence of the surfactant.[529] After a 5-min irradiation time, the FI is roughly 42 times greater than that observed in aqueous solutions. This micellar-enhanced photochemical method for mazindol has a detection limit of 3.6 ng mL^{-1} (in the absence of SDS the detection limit is 65 ng mL^{-1}).[529]

The effects of different CD media upon the photolysis of dissolved anthracene by fluorometry has been reported. Derivatized CDs promoted the photolysis reaction to a greater extent relative to the native, underivatized CDs.[191] In view of the effect of organized assemblies upon the rate of photophysical processes, it is thought that this general type of application deserves much greater attention and will lead to the development of very sensitive assays for nonfluorescent or weakly fluorescent analytes. In particular, the use of this general PIF approach as a means of HPLC detection[677] in conjunction with micellar or CD mobile phases (or run buffers) in liquid chromatography (or capillary electrophoresis or electrochromatography) should prove to be very fruitful.

3.2.3 *Fluorimetric Determination of Inorganic Ions and Organometallic Species in Organized Media*

The use of surfactant micellar systems and, to a much lesser extent, CDs can increase the stability and solubility of many organic ligands and metal complexes in water and, when such metal complexes are fluorescent, a marked enhancement in the fluorescence signal is frequently observed. Consequently, the use of such organized assemblies can improve many existing spectrofluorimetric methods by increasing their sensitivity and/or eliminating the need for extraction procedures or the use of mixed aqueous–organic solvents.[449,577,588] In addition, as has been previously noted, the possibility of conducting reactions and forming metal chelates in micellar (or other organized) media that are not observed in a bulk homogeneous solvent system can lead to new improved fluorescence methods for select inorganic species.[678–721] Some representative data in this regard is summarized in Table 8.

The fluorescence of different metal ion–morin complexes has been enhanced by the presence of surfactant micelles.[381,680–684] For example, cationic surfactants such as CTAB enhanced the intensity of Nb(V) and Ta(V) complexes, that of the former by ca. 80–400-fold.[100,628] The quantum yields of the morin–Nb(V) complex (pH 3.0) were reported as ca. 0, 0.292, 0.30, and 0.32 in water, ethanol, aqueous cetylpyridinium chloride (CPC) (hexadecylpyridinium chloride) micelles, and aqueous CTAB micelles, respectively.[381] The molar absorptivity values for the morin–Nb (V) complex at the excitation wavelength in the micellar media were greater relative to that seen in water or ethanol as bulk solvents.[381] Nonionic surfactants, such as Genapol PR-20, enhanced the intensity of the Al(III), Pb(II), and Zn(IV) complexes of morin by factors of 8.0, 9.0, and 75, respectively.[622] Triton X-100 micellar media enhanced the fluorescence observed from the morin–Ta(V) and morin–Nb(V) complexes by factors of 85 and 49, respectively.[100] The FI of the morin complexes of Zr(IV), Hf(IV), Al(III), Ga(III), In(III), and Sb(V) were enhanced by factors of ca. 2–13 in the presence of anionic SDS micellar media.[681,685]

In addition to enhanced sensitivity, the presence of organized assemblies in certain instances can serve to reduce the number of potential interferences. For example, in the fluorescence determination of Al(III) via the use of the complexing agent morin, in nonionic surfactant micelles, interference due to Cr^{3+}, Mg^{2+}, NH_4^+, and PO_4^{3-} was eliminated.[622] In fact, in the absence of micelles, phosphate ion seriously interferes with this method. However, this interference is completely eliminated owing to the presence of the micellar medium.

Dasgupta et al. conducted a comprehensive study of the fluorescence properties of the metal complexes of HQS in aqueous, mixed aqueous (water–DMF), and aqueous surfactant CTAC media.[686,687] Modest to significant increases in fluorescence intensities (enhancements in the range 1.2–10.2-fold) were observed in the presence of the surfactant CTAC medium for the metals Mg(II), Ca(II), Sr(II), Ba(II), Al(III), Cd(II), and Zn(II). The optimum pH for complex formation (and FI) was shifted (reduced) by 1–2 units in the CTAC system.[686] In addition, the pH range for maximum fluorescence was extended in this system. It was also noted that the presence of iron(III) quenches the fluorescence of these metal–HQS complexes and that the presence of the CTAC medium accentuates this quenching effect. The simultaneous determination of Al^{3+} and Zn^{2+} by first- and second-derivative synchronous fluorimetry via the use of HQS in the presence of CTAB has also been reported.[688]

Table 8 Summary of data concerning the fluorimetric determination of selected inorganic species in different organized assembly systems

Analyte	System conditions	Analytical parameters[a]	Comments	References
Al(III)	8-Quinolinol, SDS, pH 7.0	$\lambda_{ex} = 370\,nm$, $\lambda_{em} = 504\,nm$, D_L[a] $= 1.0$ ppb	Reversed phase HPLC separation with SDS micellar mobile phase; SDS enhanced FI by factor of ca. 4.3	695
	Ferron, didodecyldimethy-lammonium bromide vesicles, pH 5.8	$\lambda_{ex} = 386\,nm$, $\lambda_{em} = 493\,nm$, $D_L = 4\,ng\,mL^{-1}$	DODAB vesicles enhanced FI	151
	Acid chrome blue–black, Triton X-100, (or SDS) micelles, pH 5.5	$\lambda_{em} = 585\,nm$, $D_L = 0.16–0.40\,ng\,mL^{-1}$	Triton X-100 enhanced FI by factor of ca. 8.0	503
	HQS, CTAC, pH 6.0	$\lambda_{ex} = 380\,nm$, $\lambda_{em} = 490\,nm$, LDR $= 10–500\,\mu g\,mL^{-1}$, DL $0.50\,\mu g\,mL^{-1}$	CTAC, FIA with multisyringe based system	693
	HQS, CTAB, pH 5.5	Synchronous fluorescence, $\Delta\lambda = 107\,nm$, LDR $= 5–50\,ng\,mL^{-1}$, $D_L = 1.1\,ng\,mL^{-1}$	First and second derivative synchronous mode; CTAB enhanced FI by factor of 7.0	621
	HQS, DODAB[b] vesicles, pH 6.0	$\lambda_{ex} = 380\,nm$, $\lambda_{em} = 495\,nm$, LDR[a] $= 1–100\,\mu g\,L^{-1}$, $D_L = 1\,\mu g\,L^{-1}$	DODAB vesicles enhanced FI by factor of ca. 10	704
	Lumogallion, TX-100, pH 5.0	$\lambda_{ex} = 450\,nm$, $\lambda_{em} = 530\,nm$, DL $= 0.70$	Method validated by NIST standard and interlaboratory assessments	697
	Lumogallion, Triton X-100	$\lambda_{ex} = 522\,nm$, $\lambda_{em} = 566\,nm$, LDR[b] $= 0–2$ ppb, $D_L = 0.05$ ppb	Triton X-110 CP extraction conducted; TX-100 enhanced FI by factor of ca. 2.3	700
	Lumogallion, Brij-35, pH 5.46	$\lambda_{ex} = 484\,nm$, $\lambda_{em} = 552\,nm$, $D_L \approx 0.15$ nm	FIA method; Brij-35 enhanced FI by factor of 5.1	453
	Lumogallion, pH 5.0, Antarox CO 890[c]	$\lambda_{ex} = 365\,nm$, $\lambda_{em} = 558\,nm$, $D_L = 5 \times 10^{-10}\,g\,mL^{-1}$	Nonionic surfactant micelles enhanced FI by factor of 6.1	659
	Lumogallion, ethonium dichloride micelles, pH 6.0	$\lambda_{em} = 546\,nm$, $D_L = 0.03\,ng\,mL^{-1}$	Micelle enhanced FI by factor of 4.0	626
	Morin, pH 3.8, Genapol PF-20[d]	$\lambda_{ex} = 430\,nm$, $\lambda_{em} = 495\,nm$, $D_L = 0.2$ ppb	Nonionic surfactant micelles enhanced FI 10-fold	622
Be(II)	Morin, pH 6.0, Triton X-100	$\lambda_{ex} = 440\,nm$, $\lambda_{em} = 530\,nm$, $D_L = 0.04\,ng\,mL^{-1}$	TX-100 enhanced FI by factor of 5.0	113
Cd(II)	TSQ[e], pH 8.5, SDS	$\Delta\lambda = 135\,nm$, LDR = $15–250\,\mu g\,mL^{-1}$	Derivative synchronous mode; SDS (and Brij-35) micelles enhanced FI	634
Fe(III)	MPAQ[f], CTAB	$\lambda_{ex} = 316\,nm$, $\lambda_{em} = 528\,nm$, LDR $= 10–700\,ng\,mL^{-1}$, $D_L = 10.0\,ng\,mL^{-1}$	CTAB enhanced FI by factor of 3.0	616
	PCNPH[g], CTAB, pH 7.0	$\lambda_{ex} = 300\,nm$, $\lambda_{em} = 420\,nm$, LDR $= 0.20–1.45\,\mu g\,mL^{-1}$, $D_L = 0.028\,\mu g\,mL^{-1}$	CTAB enhanced FI by factor of 4.1	588
	HHQP[h], pH 3.5, Brij-58	$\lambda_{ex} = 470\,nm$, $\lambda_{em} = 525\,nm$, LDR $= 0–300\,ng\,mL^{-1}$, $D_L = 5.0\,ng\,mL^{-1}$	Quenching method, Brij-58 enhanced the quenching effect by factor of 1.5	659
	5-(4-methoxy-phenylazo)-8-(4-toluenesulfonamido) quinoline (MPATSQ), CTAB, (HCl) = 0.014 M	$\lambda_{ex} = 317\,nm$, $\lambda_{em} = 534\,nm$, LDR $= 2.1$ nM–$3.0\,\mu M$, DL $= 2.1$ nM	–	694
Ga(III)	Lumogallion, pH 2.0, ethonium dichloride[i]	$\lambda_{em} = 546\,nm$, $D_L = 1.0\,ng\,mL^{-1}$	Micelles enhanced FI by factor of 7–8	626

(*continued overleaf*)

Table 8 (*continued*)

Analyte	System conditions	Analytical parameters[a]	Comments	References
	PAN[j], SDS, pH 4.0	$\lambda_{ex} = 546$ nm, $\lambda_{em} = 573$ nm LDR = 5–400 ppb, $D_L = 0.8$ ppb	SDS enhanced FI by factor of 10	106
	DCMHQ[k], Triton X-100 or SDS micelles	LDR = 5–50 ng mL^{-1}, $D_{L(SDS)} = 1.6$ ng mL^{-1}, $D_{L(TX-100)} = 1.5$ ng mL^{-1}	Presence of micellar media enhanced FI	396
Hf(IV)	Morin, 0.25 M H_2SO_4, CPC	$\lambda_{ex} = 436$ nm, $\lambda_{em} = 512$ nm, $D_L = 0.01$ μg mL^{-1}	CPC micellar medium enhanced FI by factor of 2.0	707
In(III)	Lumogallion, pH 5.0, ethonium dichloride	$\lambda_{em} = 546$ nm, $D_L = 4.0$ ng mL^{-1}	Micelles enhanced FI by factor of 7–8	626
Mg(II)	HQS, pH 9.5, CTAB	$\lambda_{ex} = 393$ nm, $\lambda_{em} = 505$ nm, $D_L = 0.005$ μg mL^{-1}	Method applied for determination of Mg(II) in inorganic salts	689
Mo(VI)	Alizarin red S, pH 4.3, CTAB	$\Delta\lambda = 110$ nm, LDR = 32–4000 ng mL^{-1}, $D_L = 9.5$ ng mL^{-1}	Derivative synchronous mode; CTAB enhanced FI of the complex	623
Nb(V)	Lumogallion, pH 1.0, Triton X-100	$\lambda_{ex} = 495$ nm, $\lambda_{em} = 600$ nm $D_L = 7.77$ ppb	Triton X-100 enhanced FI by factor of 19.5	454
	Morin, CTAB, 1 M H_2SO_4	$\lambda_{ex} = 433$ nm, $\lambda_{em} = 503$ nm, $D_L = 1.0$ ppb	CTAB enhanced FI by factor of 80	100,628
	Morin, CPC, 3 M H_2SO_4	$\lambda_{ex} = 436$ nm, $\lambda_{em} = 512$ nm, $D_L = 0.5$ ng mL^{-1}	No fluorescence observed in water; in CPC micelles, complex is fluorescent	381
	Quercetin, CTAB, 0.3 M H_2SO_4	$\lambda_{ex} = 435$ nm, $\lambda_{em} = 497$ nm, $D_L = 3.0$ ppb	CTAB enhanced FI by factor of 65	100
Pb(II)	Morin, pH 3.3, Genapol PR-20[d]	$\lambda_{ex} = 420$ nm, $\lambda_{em} = 495$ nm, $D_L = 0.06$ μg mL^{-1}	Genapol PF-20 enhanced FI by factor of ca. 9.0	669
Sc(III)	Quinizarin[l], pH > 12, β-CD	$\lambda_{ex} = 545$ nm, $\lambda_{em} = 600$ nm, LDR = 0.5–400 ng mL^{-1}, $D_L = 0.15$ ng mL^{-1}	β-CD aids in the dissolution of the chelate and enhances its stability	672
Tributyltin ion	Morin, Triton X-100, pH 5.7	$\lambda_{ex} = 408$ nm, $\lambda_{em} = 534$ nm, LDR = 0.03–1.0 μg mL^{-1} $D_L = 16$ ng mL^{-1} (as Sn)	Postcolumn fluorescent detection mode; the Triton X-100 micelles solubilized the organotin and morin, enhanced FI and increased flexibility of pH requirements	629
Sn(II)	PAN, mixed TX-100 and bis(2-ethylhexyl) sulfosuccinate (AOT)	$\lambda_{ex} = 300$, $\lambda_{em} = 360$, DL = 2 ng mL^{-1}	Mixed micelles served to solubilize the tin complex and enhanced FI	674
Ta(V)	Morin, CTAB, 0.2 M H_2SO_4	$\lambda_{ex} = 422$ nm, $\lambda_{em} = 496$ nm, $D_L = 0.03$ ppm	CTAB enhanced FI by factor of 400	100
	Quercetin, CTAB, 0.05 M H_2SO_4	$\lambda_{ex} = 430$ nm, $\lambda_{em} = 485$ nm, $D_L = 0.05$ ppm	CTAB enhanced FI by factor of 37	100
Tb(III)	BPMPHD[m], Gd^{3+}, CTAB, pH 5.5	$\lambda_{ex} = 305$ nm, $\lambda_{em} = 545$ nm, $D_L = 2.0 \times 10^{-12}$ M, LDR = 2.0×10^{-11}–8.0×10^{-6}	CTAB enhanced FI by factor of 20	590
W(VI)	Alizarin red S, pH 4.3, CTAB	$\Delta\lambda = 110$ nm, LDR = 49–2500 ng mL^{-1}, $D_L = 14.7$ ng mL^{-1}	Derivative synchronous mode; CTAB enhanced FI of the complex	623
Zn(II)	TSQ[e], Brij-35, pH 7.0–8.7	$\lambda_{ex} = 367$ nm, $\lambda_{em} = 515$ nm, LDR = 8.0–550 ng mL^{-1}, $D_L = 3.0$ ng mL^{-1}	Brij-35 solubilized the Zn–TSQ complex and enhanced FI by factor of ca. 3.0	633
	DCMHQ[k], pH 6.0, CTAB or Brij-35	$\lambda_{ex} = 397$ nm, $\lambda_{em} = 534$ nm, LDR = 3–100 ng mL^{-1}, $D_L = 3.0$ ng mL^{-1}	CTAB (or Brij-35) enhanced FI by factor of ca. 25.0	624
Zn(II)	Morin, pH 4.7, Genapol PF-20[d]	$\lambda_{ex} = 433$ nm, $\lambda_{em} = 503$ nm, $D_L = 3.0$ ng mL^{-1}	Nonionic micelle enhanced FI by factor of 75.0	109
	Morin, 0.12 M H_2SO_4, CTAB	$\lambda_{ex} = 424$ nm, $\lambda_{em} = 508$ nm	CTAB enhanced FI by factor of ca. 31.0 and lowered the pK_a of morin	675

[a] D_L refers to detection limit and LDR to linear dynamic range.
[b] Refers to DDAB.
[c] Refers to nonionic surfactant nonylphenoxypoly(ethyleneoxy)ethanol.
[d] Refers to nonionic surfactant, ethylene oxide–propylene oxide condensate in which the propylene oxide : ethylene oxide ratio is 1 : 6.
[e] Refers to 8-(*p*-toluenesulfonamido)quinoline.
[f] Refers to 5-(4-methylphenylazo)-8-aminoquinoline.
[g] Refers to 2-pyridinecarbaldehyde-5-nitropyridylhydrazone.
[h] Refers to *o*-hydroxyhydroquinonephthalein.
[i] Refers to nonionic surfactant polyethylene glycol monolauryl ether.
[j] Refers to 1-(2-pyridylazo)-2-naphthol (PAN).
[k] Refers to 5,7-dichloro-2-methyl-8-hydroxyquinoline.
[l] Refers to 1,4-dihydroxyanthraquinone.
[m] Refers to 1,6-bi(1′-phenyl-3′-methyl-5′-pyrazolone)hexanedione (diacylated pyrazolone).
[n] Refers to *o*-hydroxyhydroquinonephthalein.
[o] Refers to tetradecyltrimethylammonium chloride.
[p] Refers to 3-hydroxy-2-naphthoic acid.
[q] Refers to ethylenediaminetetraacetic acid.

Fluorimetric methods for Al^{3+}, Mg^{2+}, and Zn^{2+} based upon the formation of their 8-hydroxy-7-iodoquinoline-5-sulfonic acid chelates in the presence of cationic surfactants such as CTAB have also been reported by other groups.[689–694] CTAB micelles enhanced the fluorescence observed for some of these systems, allowing better detection limits. For instance, the sensitivity of the fluorimetric procedure for Al(III) improved by a factor of 8.0 in the presence of CTAB.[690]

The use of SDS micelles in the mobile phase allowed the reversed-phase HPLC separation and fluorescence detection of Al(III) as its 8-quinolinolato complex.[695] The FI was about four times greater than in bulk homogeneous solution, allowing a limit of detection of 1.0 ppb. In another report, micellar liquid chromatography with a CTAB micellar mobile phase allowed for the determination of $10\,\mu g\,mL^{-1}$ Al(III) as its HQS complex.[696] The effect of CPB, CTAB, and Triton X-100 micellar media upon the Ta(V), Ti(V), Al(III), and Nb(V) chelates with lumogallion, ferron, quercetin (3,3′,4′,5,7-pentahydroxyflavone), morin (3,5,7,2′, 4′-pentahydroxyflavone), oxine-5-sulfonic acid (HQS), and Alizarin red S has been reported.[101,678,696,697] In most instances, the presence of these surfactant micelles dramatically enhanced the FI. Mechanistic aspects of these systems and factors impacting on the fluorescence enhancements were discussed.[101,678] The fluorescence characteristics of the gallium(III) chelate formed with lumogallion, hexyl-lumogallion, and dodecyl-lumogallion in the presence of surfactant micellar systems have been reported.[698,699] A 10-fold increase in the quantum efficiency of the Ga(III)–hexyl-lumogallion chelate was observed in the presence of the nonionic surfactant polyethylene glycol monolauryl ether.[698] Gallium was easily determined in the parts per billion (ppb) range using this micellar-modified fluorimetric procedure.

A Brij-35-enhanced FIA/fluorimetric method for the determination of aluminum(III) based on the formation of the Al–lumogallion complex has been developed.[453] The detection limit was 0.15 nM, making it one of the most sensitive assays for Al(III). The method is very sensitive, easy to use, and rapid (cycle time 3.0 min).

Triton X-100 micellar medium was utilized as the extraction medium (CP extraction procedure) to extract the Al(III)–lumogallion complex from water (extraction efficiency 72%).[700] The surfactant-rich medium also resulted in a 2.3-fold increase in the FI compared with that observed in bulk aqueous solution. The detection limit attained was 0.05 ppb Al(III).

The sensitivity of the spectrofluorimetric method for Ga(III) with 1-(2-pyridylazo)-2-naphthol (PAN) in the presence of SDS micelles is ca. 20 times better than

that obtained in a 20:80 (v/v) ethanol–water solvent system.[106]

The fluorescence reactions of Ti(IV) and Ta(V) ions with pyrogallol red, bromopyrogallol red, Alizarin red S, morin, and 8-quinolinol derivatives have been evaluated as the basis for the fluorimetric determination of these metal ions in the presence of surfactant micellar media.[701]

The effects of β-CD and hexadecylpyridinium bromide, CTAB, and SDS surfactant micellar media upon the fluorimetric properties of the metal chelate complexes formed between 2-(2-hydroxyphenyl)benzoxazole and Al(III), Be(II), Ga(III), and Zn(II) have been reported.[702]

The use of flavones (flavonol, chrysin, fisetin, quercetin, morin, etc.) as fluorescent labeling reagents for the postcolumn detection of organotin compounds has been reported.[608,703,704] The FI observed after reaction of such flavones with organotin chlorides, i.e. triphenyltin, diphenyltin, monophenyltin, tributyltin, dibutyltin, trimethyltin, and tricyclohexyltin chloride, in the presence of micellar Triton X-100 was determined. The results indicated that morin and fisetin are the most general labeling agents for organotin species, with morin being the best reagent for mono-organotin compounds and fisetin the most sensitive for triphenyltin.[608,704] The fluorescence of the flavonol complexes of mono- and diorganotin compounds was found to be greater in hexane as solvent than in the Triton X-100 system. However, the micellar system proved superior to hexane as a medium for the triorganotin complexes.[608] The system has been employed for the fluorimetric detection of organotin compounds following their HPLC separation.[703]

The fluorimetric method for determination of selenium based upon its reduction to selenite and subsequent reaction with 2,3-diaminonaphthalene to form the fluorescent 4,5-benzopiaselenol complex is enhanced in the presence of organized assemblies. For instance, the detection limit for Se in the presence of a CTAB micellar medium is 23.7 times lower than that observed in aqueous solution.[705] Another report indicated that the FI of 4,5-benzopiaselenol was enhanced by a factor of 5–6 in the presence of either SDS micelles or β-CD.[706] This enhancement factor increased to ca. 30 when the fluorescence was measured in a mixed SDS micelle–β-CD system relative to that observed in bulk water.

A few studies concerning the formation and fluorescent properties of metal chelates have been conducted in vesicle or liposome systems. In one study, the features of the Al^{3+}–8-quinolinol-5-sulfonic acid chelate in the presence of cationic DODAB vesicles were evaluated.[147] The fluorescence enhancement observed was similar to that seen in the presence of cationic CTAB micelles. However, in the case of the Al^{3+}–ferron chelate, the fluorescence signal observed in the presence of DODAB vesicles was greater than that in CTAB, Brij-35, or zwitterionic surfactant micellar media.[151] No fluorescence enhancements above that seen in aqueous solution were noted in the presence of CDs or anionic SDS micelles for this chelate. The proposed vesicle-enhanced method for Al(III) was validated by determining the aluminum content of different infant milk powders, with a detection limit of $4.0\,ng\,mL^{-1}$.[151] These results demonstrated that in some situations, a vesicle medium is superior to that of micelles or CDs and that vesicle aggregate systems can be utilized as a medium for developing more sensitive analytical methods for the determination of certain metal ions.

In addition to the determination of metal ion concentrations, different organic chelating agents have been employed for the determination of the concentration of cationic detergents, surfactants, or surface-active agents.[707,708] For instance, the use of lumogallion has been reported for the fluorimetric determination of the cationic surfactants CPB and ethonium, with detection limits of 0.027 and $0.024\,\mu g\,mL^{-1}$, respectively.[707] The method is rapid and simple and does not require the use of an extraction step to remove the excess reagent as required in other spectral methods.

Several reports have considered the general mechanism and primary factors that influence the enhancement of the fluorescence of metal chelates by surfactant micelles.[503,678,679,709,710] Solubilization and binding equilibria for reagents and metal chelates between the micelles and the aqueous phase seemed to be the most important factor governing the fluorescence enhancements observed for a number of metal ion–ligand chelates.[503,679] The presence of the micellar surfactant can also alter the coordination number of the metal ion complex,[711] which in some instances was postulated to be the reason for enhanced luminescence. There is a continuing need for comprehensive, mechanistic studies in this area. Perhaps studies reported in the physical chemistry literature could aid in this endeavor. For example, Demas and DeGraff reported on the binding interactions of a series of luminescent α-diimine complexes of ruthenium(II) and osmium(II) with SDS, Triton, and Brij micelles as studied by luminescence spectroscopy and quenching techniques.[712–714] The strength of binding and degree of solvent shielding of the complexes by the micelles were found to correlate systematically with the charge and polarity of the complexes and the hydrophobicity of the coordinated ligands. The factors responsible for the enhancement of luminescence efficiency were also identified.

Micellar (or CD) enhancement of fluorescence quenching has been employed to determine some environmentally important metal ions. For example, in the

presence of the anionic micelle, NaLS, the fluorescence of the probe molecule naphthalene was efficiently quenched by metal ions thus allowing their quantification via Stern–Volmer calibration plots (with detection limits in the range of 1–10 μM).[715] Likewise, quenching of 2,6-bis(benzoxazolyl)pyridine in a β-CD medium allowed the selective determination of the iron(III) ion.[716] Anions can also be determined via micellar-amplified quenching. For example, as shown in Figure 8, the slope of the Stern–Volmer plot for the quenching of *N*-methylacridone by iodide ion in the presence of a cationic DTAC micelle medium is much greater (factor of ca. 11) than that observed in bulk aqueous solution alone, which translates into a lower limit of detection for the iodide ion.[717]

A Triton X-100 micelle system containing the fluorescene pyrene molecule and the chelating agent dodecyldioxo-2,3,2 has been proposed as a sensor for transition-metal ions.[718] The sensor action is based on the transition metal ion's ability to quench the pyrene probe fluorescence.

3.2.4 *Lanthanide- (or Ligand-) Sensitized Fluorescence in Organized Assemblies*

The sensitization of the fluorescence of lanthanide and actinide ions by organic ligands is well known and has been extensively utilized during the past two decades in various analytical applications, including immunoassays, quantification of organic compounds, chromatographic detection schemes, etc.[719–723] In particular, europium, terbium, samarium, and curium are known to form highly fluorescent chelates with a variety of organic ligands, often in the presence of a so-called synergistic agent. The intense sensitized fluorescence results from excitation of the organic ligand donor molecule, the energy of which is in part transferred (intramolecular energy transfer step) from its excited triplet (or singlet) state to the emitting level of the chelated lanthanide (or actinide) ion acceptor, resulting in ion-specific emission, and is characterized

Figure 8 Stern–Volmer plots for quenching of *N*-methylacridon's fluorescence by iodide ion in aqueous solution (open circles) and in an aqueous solution containing DTAC surfactant micelles (dark circles). Conditions: [*N*-methylacridone] = 5.0×10^{-6} M; $\lambda_{ex} = 384$ nm; $\lambda_{em} = 422$ nm; [DTAC] = 0.030 M.

by large Stokes shifts, narrow (line-type) fluorescence bands, and long lifetimes. These properties allow spectral discrimination of the analytical signal and/or temporal time discrimination that eliminates (or greatly diminishes) background fluorescence and scattering signals and allows time-resolved signal accumulation such that very sensitive and selective fluorimetric methods can be developed. For a more detailed, quantitative discussion of this topic, the interested reader is referred to published review articles.[719,720]

In some cases, an intermolecular energy transfer from the triplet level of an organic sensitizer directly to the unbound lanthanide ion has been reported.[604,724] Such an intermolecular energy transfer process in a homogeneous solution is typically inefficient. However, intermolecular energy transfer from organic species to lanthanide ions in aqueous micellar solution has been observed.[275,604,725] For instance, efficient energy transfer has been observed from SDS micellar solubilized naphthalene to terbium(III).[275] Likewise, very efficient energy transfer from the 2-acetylnaphthalene triplet to Eu^{3+} was observed in SDS micellar solution.[371] Such intermolecular energy transfer may be observed only by the use of organized media to bring the donor and acceptor molecules into close proximity and substantially increase their effective local concentrations.[275,567,604,726] Since micelles solubilize the ternary complexes and can increase the efficiency of intermolecular energy transfer and also favorably impact luminescence parameters as previously described, they have been employed as enhancers in lanthanide-sensitized fluorescence assays. In particular, lanthanide ions exhibit low emission quantum yields in water. However, when complexed with appropriate ligands and solubilized in micellar media, intense, sharp emission bands are observed since the added agents help to "remove" water from the lanthanide ion's primary solvation shell, thus preventing quenching of the excited state by water molecules.[720] In addition, the fluorescence lifetimes of the lanthanide complexes are greater.[727,728] For example, the lifetime of the europium chelate of thenoyltrifluoroacetone (TTA) in ethanol was 180 μs, whereas it is 780 μs in the presence of Triton X-100 micelles and trioctylphosphine oxide (TOPO).

A comparative study of the fluorescence efficiency in the Eu^{3+}–TTA–TOPO chelate in ethanolic and aqueous Triton X-100 media has been conducted.[728] It should be noted that large enhancements in the yield of intramolecular charge-transfer emission from organic molecules have also been observed in CD media.[550] A comparative investigation on the effect of cationic micelles upon the fluorescence observed from the Eu^{3+} (and Tb^{3+}) complexes with Tiron, salicylic acid, acetylacetone, and 4-sulfonyl salicylic acid has been reported.[729] Such lanthanide ion–organic

ligand–synergistic agent–micellar systems have been employed to determine the concentration of either the lanthanide–actinide ions or organic species that can act as ligands, as well as for time-resolved fluoroimmunoassays of a number of biological/clinical compounds.[719,730,731] In general, for determination of lanthanide or actinide ions, a sensitizer organic ligand that can form a tris-chelate to the ion, such as a diketone (e.g. TTA), is employed along with a strong donor ligand (synergistic agent), such as TOPO (or other organic phosphates, e.g. tributyl phosphate or sulfoxides), which can compete with water for inner coordination sites, and surfactant micelle.[732] This approach for the determination of lanthanides or actinides is termed *ligand-sensitized fluorescence*. The micelle system typically serves to solubilize the syngeristic agents (as TOPO) and the ternary metal complexes in aqueous solution and enhances the fluorescence.[733–740] In addition, it has been postulated that the presence of the micellar medium alters the enol–ketone equilibrium ratio (ratio of ca. 0.016 in water and 20.0 in benzene) of the diketone (TTA) reagent so that the chelating properties of the enol form, which favors formation of the lanthanide–actinide chelate, predominates.[741] β-CD can also shift such keto–enol equilibria toward the enol tautomeric form[252]; however, its use in such lanthanide-sensitized systems has apparently not yet been reported. The partition behavior of some Eu^{3+}–diketone–TOPO adducts between nonionic surfactant micellar and bulk aqueous phases has been investigated.[742] The use of time-resolved laser-induced spectrofluorimetry has been employed for the study of uranium–surfactant micelle[743] and Eu^{3+}–phospholipid vesicle[744] interactions. The fluorescence properties of terbium(III)–phospholipid complexes have been reported.[745] A thermodynamic study of the inclusion complexes formed between trivalent lanthanide ions and native CDs has been conducted.[277] The luminescent properties of the tris(dibenzoylmethane)europium(III) dihydrate–β-CD complex in the solid state have been reported.[746] It might prove interesting to examine the luminescent behavior of lanthanide ions and their diketone complexes in the presence of crown ether–based surfactant micelles. For example, the binding of Gd^{3+} to 1,4,7,10-tetraazacyclododecane-1-[1′-carboxy-1′-dodecyl(methyl)aminooxoethyl]-4,7,10-triacetic acid (DOTA) (CMC = 0.35 mM) has been examined in the context of its ability to function as a magnetic resonance imaging (MRI) contrast agent.[747] This system might prove to be interesting from the analytical luminescent viewpoint as well.

As for examples of the general utilization of this sensitized fluorescence technique, the determination of europium, terbium, and samarium ions was reported via use of TTA (or pivaloyltrifluoroacetone (PTA)) and TOPO in aqueous solution containing the nonionic surfactant nonaoxyethylene dodecyl ether ($C_{12}E_9$).[748–752] The stoichiometry and complex equilibrium involved with this system have been determined.[733] Europium(III) ($\lambda_{ex} = 355$ nm, $\lambda_{em} = 615$ nm) was determined in the 10^{-11}–10^{-5} M range with a detection limit of 6.0×10^{-12} M via formation of the $Eu(TTA)_3(TOPO)_2$ complex in an aqueous Triton X-100 micellar medium.[734] For this system, the effectiveness of different nonionic surfactant micelles with respect to increasing the FI observed from this complex (or that of the corresponding Tb^{3+} complex) followed the order Triton X-100 > octylphenol ethoxylate (Triton) surfactants (OP) > Tween 80 systems.[740] Instead of the use of TTA or TOPO as the organic chelating and synergistic agents, a number of other organic ligands/agents have been proposed and evaluated.[732,753] Examples of such systems include TTA–phen–Triton X-100 (or Polysorbate 20),[754–756] 2-naphthoyltrifluoroacetone (NTFA)–TOPO–Triton X-100,[757] sodium benzoate–TOPO–Triton X-100,[735] 2-benzoylindan-1,3-dione (BID)–TOPO–Triton X-100,[736] TTA–diphenylguanidine–Triton X-100,[110] PTA–2,2′-bipyridine (BP)–Triton X-100,[758] hexafluoroacetylacetone (HFAC)–TOPO–Triton X-100[759] trimesic acid (benzene-1,3,5-tricarboxylic acid)–TOPO–Triton X-100,[760] and benzoic acid derivatives–TOPO (or EDTA)–CTAC[761] among others. The fluorescence observed from Tb, Dy, or Eu using benzoate (or trimesic acid) as the chelating ligand in the presence of TOPO and Triton X-100 micelles was enhanced by almost 4 (or 3) orders of magnitude compared to the use of diketone ligands.[735,760] With the lanthanide–benzoate–TOPO–Triton X-100 system, the detection limits for lanthanides (Dy, Tb, Eu) were in the 10^{-9}–10^{-10} M range.[735] A detection limit of 4.0×10^{-9} M Eu^{3+} was reported for the BID–TOPO–Triton X-100 system.[736] In addition to use of Triton X-100, the nonionic surfactant Tween 20 has also been employed as the micellar entity. A detection limit of 50 ppt Dy^{3+} was reported for the TTA–TOPO–Tween 20 system.[762] Dysprosium(III) ion was determined at concentrations as low as 1.0×10^{-9} M using the EDTA–Tiron–CTAB system.[763] The fluorescence signal observed in this system was ca. 12.3 times greater in the CTAB (or cetyldimethylbenzylammonium chloride) micellar systems than that observed for Triton X-100.[763] A detection limit of 20 pM Tb^{3+} was reported via use of an unoptimized 1,1,1-trifluoro-2,4-tridecanedione (TFTD) or 1,1,1-trifluoro-5,5-dimethyl-2,4-hexanedione (TFDMH)–TOPO–Triton X-100 system.[732] Terbium (III) has also been determined via use of the PTA–TOPO–$C_{12}E_9$ system in the flow injection mode with a detection limit of 16 ng mL^{-1}.[764] Tb^{3+} was also determined down to the 0.003 ng mL^{-1} level

using the system Tiron–imidodiacetic acid–CTAB.[739] Determination of curium at the $0.10\,ng\,mL^{-1}$ level in a micellar medium by this approach has been reported.[741] Thulium(III) and yttrium(III) were determined down to 1.0×10^{-7} M and $1.8\,ng\,mL^{-1}$, respectively, using the system bis(1′-phenyl-3′-methyl-5′-pyrazol-4′-one)hexanedione–CTAB.[581,765] The presence of the CTAB enhanced the FI of these Th^{3+} and Y^{3+} chelates by a factor of ca. 25 and 8, respectively. Curium(III) has been determined at the $0.10\,ng\,L^{-1}$ (5×10^{-13} M) concentration level using the TTA–TOPO–Triton X-100 system.[629] The fluorescence observed from the ytterbium(III)–4-(2-pyridylazo)resorcinol–CTAB (or CPB or chloride) system was 2.8–4.5 times greater than in the absence of the cationic CTAB or cetylpyridinium salt surfactant media.[749] This enhancement was attributed to the greater rigidity of the micellar bound complex.

Hence these assays are superior to the traditional solvent extraction methods that have been employed for determination of these lanthanide/actinide ions, in terms of not only their simplicity and speed, but also their sensitivity.[748]

It has been reported that the presence of certain other ions, such as La, Gd, Lu, or Y, can lead to additional enhancements of the fluorescence observed from the chelates of Tb, Eu, and Dy. This is referred to as the *columinescence* (or *cofluorescence*) *effect* (Xu et al.[766] have reviewed this topic). This effect is based on an intermolecular energy transfer from the chelates of the enhancing ion (such as Gd^{3+} or Tb^{3+}) to the chelates of the emitting ion (such as Eu^{3+} or Sm^{3+}).[766] Fluorescence enhancement of rare earths due to columinescence has been reported using β-diketone ligands as the energy transfer agent along with TOPO or BP as synergistic ligands and Triton X-100 micelles.[758] Detection limits for Eu^{3+}, Tb^{3+}, and Sm^{3+} were reported as 0.019, 0.27, and 3.8 pM, respectively for the PTA–BP–Triton X-100 system containing added yttrium(III) cation.[758] These detection limits were slightly better than those reported for the PTA–phen–Triton X-100 system with added Y^{3+} for these three metal ions.[767] The addition of gadolinium(III) to the system containing samarium or europium(III) ions with TTA–phen–Triton X-100 resulted in 1–2 orders of magnitude better sensitivity for the determination of Sm^{3+} or Eu^{3+} compared to that observed in its absence.[768] The specific detection limits reported were $(5.0–7.5) \times 10^{-10}$ M for samarium and 7.5×10^{-12} M for europium.[769,770] Substitution of 4,7-diphenyl-1,10-phenanthroline for phen in this general system led to a detection level of $0.6\,pg\,mL^{-1}$ for Eu^{3+}.[771] A detection limit of 10 pM for Eu^{3+} was reported for the system TTA–phen–Triton X-100 in the presence of Lu(III).[772] Use of the TTA–TOPO–CTAB system with added gadolinium(III) allowed the determination of europium(III) with a detection limit of 8.0×10^{-11} M.[737] A slightly more sensitive method (detection limit 2.6×10^{-11} M) for europium(III) was achieved using the system dibenzoylmethane (DBM)–CPC in the presence of Gd^{3+} and triethanolamine.[773] A detection limit of 3.0×10^{-12} M Eu^{3+} was reported for the diphacinone [2-(diphenylacetyl)indan-1,3-dione]–ammonia–Triton X-100 system containing La^{3+} ion.[616] Using the TTA–CTAB–Triton X-100 system in conjunction with Gd^{3+} also allowed the determination of Eu(III) with a reported detection limit of 2.0×10^{-12} M.[738] Detection limits of 4–15 fM were reported for the TTA (or benzoyltrifluoroacetone (BTA))–phen–Triton X-100 system containing added yttrium(III) ion.[774] In the determination of europium(III) via use of the TTA–phen–surfactant system containing terbium(III), the relative luminescence intensity as a function of the specific surfactant micelle system followed the order Triton X-100 > Tween 20 > polyoxyethylene lauryl ether > SDDBS > CTAB > CPC.[754] Under optimized conditions using Triton X-100 micellar media, a detection limit of 1.0×10^{-13} M Eu(III) was reported.[754] The use of mixed ligand complexes of TTA and 1,10-diaza-15-crown-5 in the presence of CTAB and Gd^{3+} (or other lanthanides) also allowed the determination of ppb levels of Eu(III).[775] The reagents Y^{3+}–TTA–CTAB and Y^{3+}–sparfloxacin–SDS were utilized to determine Eu^{3+}, with a detection limit of 1.0×10^{-11} M[776] and 1.0×10^{-13} M,[777] respectively. A similar detection limit for Eu(III) was reported for the reagent system composed of Gd^{3+}–ofloxacin–sodium dodecylbenzenesulfate micelles.[730] The presence of the Triton X-100 or CTAB micelles in these reagent combinations was thought to enhance the interchelate energy transfer, protect the chelates against the quenching effects of water molecules, and stabilize the fluorescence in such systems.[737,754,758,766,768] Cationic surfactants can function as a cation in the ternary complex that forms in some instances.[738,778] Typically, there is an optimum surfactant concentration beyond which further increases in concentration lead to decreased fluorescence. This is the result of dilution of the system with increasing micelle concentration so that the probability that both donor chelate species and acceptor fluorescent species are bound to the *same* micelle is decreased.[766] Separation of the donor and acceptor in different micelles obviously decreases the efficiency of the intermolecular energy transfer step with a resultant diminution in the FI.

To the best of our knowledge, there are no reports concerning the examination of such systems for the determination of lanthanides/actinides in the presence of CD or vesicle organized assemblies. However, enhanced fluorescence was observed for Eu^{3+}–TTA–phen in the

presence of Tb^{3+} (or Gd^{3+})–TTA–phen when confined in Langmuir– Blodgett films.[779] In addition, there is one report concerning the synthesis of polymerized fluorescent liposomes that incorporate lanthanide ions.[780]

Energy transfer from an organic compound to the lanthanide ion can also be utilized to improve the fluorimetric determination of organic analytes that can chelate the metal ion. This approach for assaying organic components is referred to as *lanthanide-sensitized luminescence* (for a review see Georges[719]). A number of reports indicate that the presence of micelles can further intensify the luminescence intensity of such systems and improve the sensitivity. Methyl anthranilate in food samples, after hydrolysis to *o*-aminobenzoic acid, was determined by the sensitized luminescence obtained from the Tb^{3+}–TOPO–aminobenzoic complex in the presence of TX-100. This approach was applied with success for analysis of methyl anthranilate and adenosine triphosphate (ATP) in a variety of food and drink samples.[781,782] The antibiotics ciprofloxacin, enrofloxacin, and levofloxacin have also been determined via terbium-sensitized luminescence in the presence of SDS micelles[783,784] or sensitized fluorescence of europium in the presence of 1,10-phenanthroline in SDDBS micelles.[752] Tetracyclines (such as doxycycline, oxytetracycline, demeclocycline, methacycline, and chlortetracycline) have been determined using europium-sensitized fluorescence with EDTA as a coligand in the presence of CTAC micelles.[731,785]

Table 9 summarizes other representative applications of the lanthanide-sensitized luminescence for the determination of organic compounds in the presence of

Table 9 Summary of micellar-enhanced lanthanide-sensitized determination of organic species

Analyte species	Lanthanide ion	Micelle system/conditions	Comments	References
Tetracyclines (9)	Eu(III)	Triton X-100 or CPC, pH 8.0, $\lambda_{ex} = 394$ nm, $\lambda_{em} = 618$ nm, $D_L \approx 2 \times 10^{-7}$ M	Micelles enhanced luminescence intensity by factor of up to 34	617
Tetracycline	Eu(III)	Triton X-100, pH 7–8.5, $\lambda_{ex} = 390$ nm, $\lambda_{em} = 613$ nm, $D_L = 3.0 \times 10^{-9}$ M	TX-100 enhanced FI by factor of 5 (at pH 9) to 12.5 (at pH 7)	719
Diphacinone	Eu(III)	Triton X-100, pH 8.5, $\lambda_{ex} = 336$ nm, $\lambda_{em} = 619$ nm, LDR = 0.5–5.0 μg mL^{-1} D_L = 0.20 μg mL^{-1}	No fluorescence observed in absence of surfactant	780
Pindone	Eu(III)	CTAB, Triton X-100, TTA, pH 6.4, $\lambda_{ex} = 273$ nm, $\lambda_{em} = 614$ nm, LDR = 0.1–10.0 μg mL^{-1}, $D_L = 0.04$ μg mL^{-1}	Indirect kinetic method, CTAB enhanced intensity of fluorescent reagent complex	778
Benzoic acid (BA) and saccharin (S)	Tb(III)	Triton X-100, TOPO, pH 6.0, $\lambda_{ex} = 284$ nm, $\lambda_{em} = 545$ nm, $D_{L(BA)} = 0.04$ μg mL^{-1}, $D_{L(S)} = 1.1$ μg mL^{-1}	Triton X-100 noticeably enhanced the luminescence signal, kinetic method	602
Salicylic, fluorosalicylic and aminosalicylic acids	Eu(III)	CTAC, EDTA, pH 12, $\lambda_{ex(SA)} = 330$ nm, $\lambda_{ex(FSA)} = 335$ nm, $\lambda_{ex(ASA)} = 310$ nm, $\lambda_{em} = 545$ nm, $D_L = (2–4) \times 10^{-10}$ M	CTAC micelles enhanced FI 10-fold	618
Propyl gallate	Tb(III)	SDS, Triton X-100, pH 6.5, $\lambda_{ex} = 310$ nm, $\lambda_{em} = 545$ nm, LDR = 0.08–3.0 μg mL^{-1}, $D_L = 0.02$ μg mL^{-1}	Triton X-100 solubilized the Tb^{3+}–SDS chelate and enhanced the initial rate of this kinetic method	112
Orotic acid	Tb(III)	CTAB, pH 6.0, $\lambda_{ex} = 325$ nm, $\lambda_{em} = 544$ nm, LDR = 10^{-7}–5×10^{-5} M, $D_L = 5 \times 10^{-8}$ M	CTAB enhanced FI and lowered the second pK_a of analyte, analyte detected following MEKC[a] with CTAB	619
Steroids (6)	Tb(III)	SDS, $\lambda_{ex} = 247$ nm, $\lambda_{em} = 547$ nm, $D_L = 100$ pg mL^{-1} (for bolasterone) to 3000 pg mL^{-1} (for cortisone)	SDS enhanced FI of steroidal–Tb(III) chelates, analytes detected following MLC[b] with SDS	790
	Tb(III)	SDS, $\lambda_{ex} = 238$ nm, $\lambda_{em} = 520$ nm, pH 7.0	Demonstrated use of SDS in run buffer for enhanced energy transfer and CZE separation	619

[b] Micellar liquid chromatography, which employed aqueous solutions of surfactant micelles as the mobile phase.

surfactant micellar media.[112,602,617–619,719,778–791] Also, the addition of lanthanide ions, such as Tb^{3+}, to PAHs solubilized in NaTC bile salt micelles generally resulted in enhanced fluorescence.[121,786] Detection limits for the determination of the PAHs anthracene, perylene, benzo[*k*]fluoranthene, pyrene, and benzo[*ghi*]perylene were in the range 0.021–0.70 nM in the Tb^{3+}–NaTC system.[121] As noted by Georges, the application of this general method is not limited to the examples just mentioned or shown in Table 9, but is also potentially valid for many other organic species, provided that they exhibit large molar absorptivities and have the ability to function as energy donors with respect to a lanthanide ion.[719,787]

More recently, quenching of lanthanide complexes in micelles has been utilized to determine the quencher concentration. Addition of ATP to the Eu(III)/Gd(III) complex with TTA in nonionic Brij-35 micelles diminished the observed luminescence fom this complex and allowed the determination of ATP (detection limit 8.0×10^{-8} M) in fruit juice samples.[782]

Amino- and mercapto-containing compounds have been detected following HPLC separation using lanthanide-sensitized fluorescence.[111] In this detection scheme, a precolumn derivatization method was employed in which the amino compounds were reacted with the Eu^{3+} chelate of *N*-(*p*-isothiocyanatobenzyl) diethylenetriaminetetraacetic acid (IDTTA) (or Eu^{3+} chelate of 1-[*p*-([(5-maleimidopen-tyl)carbonyl]amino} benzyl)ethylenediaminetetraacetic acid (MEDTA) in the case of thiols) and resolved via reversed-phase HPLC. Next, a postcolumn derivatization step is conducted in which the labeled Eu–IDTTA–amino compounds (or Eu–MEDTA–thiols) are reacted with the reagent NTFA–TOPO–Triton X-100, which results in formation of the highly fluorescent Eu^{3+}–NTFA–TOPO chelate. For thiols, the detection limits reported ranged from 13.2 to 18.8 fmol.[111] The presence of Triton X-100 micelles was necessary for observation of enhanced fluorescence. Terbium-sensitized fluorescence was utilized as a detection mode in HPLC for 14 different steroidal hormones which were eluted with an SDS-containing mobile phase (detection limits ranged from 0.08 to 0.55 $\mu g\,mL^{-1}$).[788] Use of Eu^{3+}–TOPO–Triton X-100 (pH 10.5) as a postcolumn derivatization reagent allowed the sensitive time-resolved sensitized luminescence detection of tetracyclines following their HPLC separation.[789] Use of Tb^{3+}–CTAB allowed the sensitive fluorimetric determination of 2,6-dihydroxypyrimidine-4-carboxylic acid following capillary electrophoretic separation using CTAB in the run buffer.[619] This method required no sample pretreatment and was free of any known interference in the urine samples examined. Micellar HPLC with SDS mobile phases in conjunction with sensitized terbium fluorescence detection allowed the development of a superior analytical method for semiquinoid steroids.[790] The method was sensitive, selective and simple, and allowed the direct injection of urine on to the column without the need for any sample preparation step.

Numerous reports concerning the dissociated enhanced lanthanide fluoroimmunoassay (DELFIA) technique for determination of clinical/biological analytes have appeared in the clinical/medical literature (reviews are available).[791–796] The DELFIA technique was based on the work of Hemmila et al. DELFIA involves the use of an immunocomponent (antibody, etc.) labeled with a lanthanide metal (i.e. Eu^{3+} or Sm^{3+}) chelate which is nonfluorescent. Typically, the binding of the lanthanide(III) ion to an immunoreactive component is accomplished via use of polycarboxylic derivatives (EDTA, glycol-bis(2-aminoethylether)-*N,N,N′,N′*-tetraacetic acid (EGTA), diethylenetriaminepentaacetic acid (DTPA)) that contain a suitable functional group required for covalent coupling. Such polycarboxylates have very large lanthanide ion–binding constants, but are strongly pH dependent. The immunoassay can be conducted as either a noncompetitive or competitive reaction in a solid-phase system. The amount of immunoconjugate is determined by dissociation of the lanthanide ion from the immunocomponent on the solid phase. This is accomplished by lowering the pH (pH < 4.0, which lowers the stability of the chelate complex) with the dissociated lanthanide ion going into an aqueous solution that contains the ''enhancement agents'' (i.e. β-diketone or other sensitizer, synergistic agents such as TOPO, and micelle-forming surfactant). The enhancement agents greatly intensify the fluorescence as previously noted, and in DELFIA, time-resolved intensity measurements are made to eliminate noise and increase sensitivity.[720,791] In such systems, the label may be detected in concentrations as low as 10^{-17} mol of Eu^{3+} per microtitration well.[797] The general system has been successfully applied for the assay of the following analytes in human serum: cortisol, thyroxine, α-fetoprotein, ferritin, thyrotropin, prolactin, lutropin, choriogonadotropin, follitropin, prolactin, chorionic gonadotropin, hepatitis B surface antigen, luteinizing hormone, somatotropin, digoxin, thyroxine-binding globulin, thyroid-stimulating hormone, follicle-stimulating hormone, immunoreactive trypsin, creatine kinase, 17-α-hydroxyprogesterone, progesterone, carcinoembryonic antigen, and rubella IgG and IgM antibodies,[690,720,758,774,794,791,798–801] among many others. Sensitive cytotoxicity assays using DELFIA with Eu–DTPA have been developed.[801] The utilization of chelated terbium as a label in fluorescence immunoassays has also been reported.[802,803] The cofluorescence enhancement systems are also suited for use in double (or multi) label time-resolved fluorimetric

immunoassays.[720,758,766,767,774] A review of the cofluorescence effect as it pertains to time-resolved fluoroimmunoassays is available.[766]

More recently, liposomes have been employed in steady-state and time-resolved fluoroimmunoassays for clinical/biological analytes.[804–808] Liposomes can incorporate fluorescent labels (including fluorescent lanthanide chelates), either encapsulated within their inner aqueous region (polar species) or embedded in the lipid membrane (nonpolar or amphiphilic species). In an assay dubbed ''complement immunolysis'', recognition of an analyte by an antibody (or other species) triggers the release of thousands of reporter molecules which are subsequently detected by fluorescence (or other means).[804] The large number of molecules released thus provides substantial amplification of the original antibody recognition event.[805] Such encapsulated contents can also be released upon lysis of the liposomes and the assays developed in the usual manner as in DELFIA protocols. Haptens have been determined via this approach.[808]

4 SOME GENERAL EXPERIMENTAL CONSIDERATIONS

The chemicals required for the preparation of the organized assembly systems are all commercially available. Cognizance should be taken of the purity of the surfactant or CD preparations utilized to prepare the solutions required for analytical luminescence applications. Although highly purified CDs do not fluoresce, some less purified formulations sometimes contain fluorescence impurities due to the preparation scheme employed in their purification. This is probably the cause of some reports in the analytical literature which note that CDs are strongly fluorescent.[107,108] or quench fluorescent solutes.[809] In addition, the presence of fluorescent impurities in commercial nonionic and some cationic surfactant preparations has been noted.[455,686] Weak fluorescence from NaDC solutions has also been reported when a He–Cd laser was employed as the excitation source.[646] Quenching impurities in other commercial preparations have also been reported.[178] In particular, peroxides can be present in nonionic surfactant preparations.[660] The presence of quenching impurities in the preparations can have severe detrimental effects upon the desired fluorescence measurement. Purification procedures for various surfactants and CDs are available in the literature.[195,660,810] In addition, high-purity commercial preparations are now available for many of the surfactants or CDs required in fluorimetric applications. However, there are still some recent reports that note that while CDs and surfactant micelles elicited strong enhancing effects on analyte fluorescence emission, the relative standard deviations were quite high ''likely the result of intense signals given by the [organized assembly] blanks'' which precluded their use in the desired fluorescent method.[811]

Also, for most applications, care should be taken to avoid the use of organized assembly materials that are themselves inherently fluorescent. For example, surfactants containing an aromatic ring, such as the Tritons, Igepals, Nonidets, alkylpyridinium salts, alkylbenzenesulfonates (e.g. SDDBS), and benzyldimethylhexadecylammonium halides, should probably be avoided since their use could give rise to high background fluorescence at the desired analytical emission wavelengths.[107,453,812] In addition, the pyridinium surfactants can act as potent quenchers toward many organic analytes.[107,535] The reduced forms (nonaromatic ring system) of some of these materials, such as reduced Triton X-100, are commercially available, but are more expensive.

Some surfactant micelles, such as CTAB, SDS, and Tergitol XD, present solution preparation difficulties.[220,453] That is, the preparation of the more concentrated stock solutions of such surfactants requires warming/heating the solution in order to ensure complete dissolution of the solid surfactant material.[220,404,628,679,813] Surfactants such as CTAB, TDSS, and sodium hexadecylsulfate have Krafft points that are well above room temperature. For instance, the Krafft point of SDS is ca. 16–23 °C.[180,220] Thus, when using such surfactant micelle systems, the luminescence measurements have to be conducted at an appropriate temperature (i.e. experimental temperature above the Krafft temperature) in order to prevent precipitation of the surfactant. Alternatively, it is often more convenient to utilize other micelle-forming surfactants to produce the same desired effects. For instance, CTAB has a Krafft temperature of ca. 17–20 °C, whereas that of CTAC is ca. 11 °C.[180,618] Hence CTAC is preferred to CTAB (which also has the bromide ion which can quench excited states of some organic species).

It should be mentioned that heating the aqueous solutions of some nonionic surfactant solutions can lead to phase separation (CP) behavior, where the surfactant-rich phase separates from the bulk aqueous (surfactant-depleted) phase.[659,660] The CP temperatures for typical nonionic surfactant solutions have been compiled.[659] In order to avoid complications from such phase separation, as has been reported in the literature,[814] one should utilize such surfactant micelle solutions at a temperature well below their usual CP temperature. Materials that are toxic, such as the surfactant myristylammonium bromide, should be avoided.[453] Surfactants containing heavy-atom counterions (such as Br or I) or other moieties (such as pyridinium ion) could quench certain organic molecules' excited states. Hence this fact should

be taken into account for surfactants such as CTAB, tetradecyltrimethylammonium bromide (TDAB), and alkylpyridinium salts.[249,588,813]

Whereas the solubilities of α- and γ-CD are ca. 14.5 and 23.2 g per 100 mL in water, respectively, that of β-CD is only 1.85 g per 100 mL.[161] Thus, when employing β-CD in fluorescence measurements, it is sometimes not possible to achieve the proper (high) concentrations required to produce maximum benefits.[380] In such cases, the use of β-CD derivatives that are much more soluble in water, such as hydroxypropyl or methylated β-CDs, or aqueous urea solutions, which serve to solubilize the β-CD, is recommended.[380,815] Alternatively, water–cosolvent mixtures can be employed in order to increase the β-CD concentration.[816] When utilizing CD media in analytical derivatization reactions under basic conditions, cognizance should be made of the ability of CDs to catalyze hydrolysis reactions which might interfere with the desired analytical reaction.[817] Degradation of organized assemblies on storage can lead to unexpected behavior in use, and perhaps give rise to misleading interpretation of results.[94] In this regard, it should be recognized that some organized assembly media, such as the CDs and anionic alkylsulfate surfactants, are susceptible to acid-catalyzed hydrolysis, particularly when heated or subjected to long-term storage under very acidic conditions.[94,160,161,395,818] Hence stock solutions of such organized media should not be stored for a long time under very acidic conditions. Under very basic conditions, CDs can ionize (the pK of their hydroxyl groups is in the range 12.0–12.4).[160,277] Nonionic surfactants can form peroxides during storage. Some commercial formulations have added oxidizing agents present,[94] which might also interfere with fluorescence measurements.

Experimental protocols for the preparation of solutions required for the determination of fluorescence enhancement factors in the presence of an organized assembly system relative to that in a bulk solvent have been proposed.[206,819] Differences in some of the fluorescence parameters have been noted depending upon how the solute solutions are prepared (i.e. mixing via ultrasonication vs stirring of the solutions).[180] For fluorescence measurements in all organized assembly systems, appropriate background (reference) solutions should be prepared without the analyte molecule present in order to correct for possible contributions of light scattering to the observed analytical signal.[571,820] In some cases, the appropriate use of filters can minimize the effect of scattered light.[820] However, for reproducible results, it is probably best if the precautions that have been recommended in papers concerning basic investigations of such systems also be employed in their use in chemical analysis applications. For instance, vesicle solutions should be prepared and used within 24–48 h of their preparation, with storage in the dark under N_2 at 4 °C when not in use.[198,295,821] Care should be taken during all vesicle preparation steps to avoid undue exposure to light.[198,339,508,821] In many instances, proper "aging" (equilibration) of vesicle analyte–containing solutions is required in order to obtain reproducible spectral data.[148] Depending on the conditions and additives present, some liposome-containing systems can undergo time-dependent fusion with resultant formation of larger vesicle membranes (see Figure 9).[150,153,822,823] Deliberately keeping the amphiphile concentration as low as possible minimizes such fusion.[824] Fluorescence techniques are available to monitor the time course of vesicle fusion.[150,822,825] Thus, the best reproducibility is typically obtained in analytical applications by using vesicle/liposome systems of the same "age". Greater fluorescence enhancements are typically observed in vesicle/liposome media when the measurements are conducted at a temperature below the phase transition temperature (T_M) (also referred to as the *crystal-to-liquid crystal temperature*).[148] Likewise, some aging effects have been reported for micellar solutions.[190,826–828] Hence, in many studies, aqueous stock solutions were always prepared fresh daily or utilized within a specified time frame in order to avoid errors due to such aging and allow time for equilibration of reagents within the organized assembly system.[95,423,454,813,826]

In many instances, it is necessary to bubble nitrogen through the organized assembly solutions in order to displace oxygen so as to avoid its quenching effect upon some analytes[75] or the possibility of undesired photooxidation reactions.[385] For example, the FI of the analytes benzo[*a*]pyrene, chrysene, benzo[*ghi*]perylene and pyrene in oxygen-free solutions are 2.9, 2.7, 6.4, and

Figure 9 Oversimplified diagram (cartoon) illustrating the vesicle–vesicle fusion process which results in the formation of a larger aggregate entity with decreased membrane curvature and an increase in the hydrophobic to hydrophilic surface ratio. (Adapted with permission of the Royal Society of Chemistry from B.C.R. Guillaume, D. Yogev, J.H. Fendler, *J. Chem. Soc., Faraday Trans.*, **88**, 1281–1284 (1992).)

9.0 times greater, respectively, than those observed in oxygenated solution.[829] Oxygen is ca. 20 times more soluble in air-saturated alkane solvents than in water.[364] In fact, the solubility of oxygen in water is only ca. 1% (by mass) of that observed in hydrocarbon solvents.[713] The oxygen concentration at 25 °C in micellar CTAB, SDS, and Tweens was reported to be ca. 0.13, 0.12, and 0.13–0.23 mM, respectively,[830] whereas that in solutions of sodium octanoate ranged from 1.28 to 1.57 mol O_2 per atmosphere in 1000 g of H_2O.[831] Another report indicated the oxygen solubility in water as 1.41 mM, whereas that in SDS was 1.47 mM; in another, the water solubility of oxygen was reported as 0.265 mM and in SUV vesicles as 0.85 mM.[713] The solubility of atmospheric oxygen in water in the presence of several anionic surfactants at different temperatures and surfactant concentrations has been reported.[832] The solubility of oxygen in common solvents (such as water, alcohols or cyclohexane) at 25 °C and 1 atm has been compiled.[833]

One problem with the use of surfactant or micellar solutions arises when deoxygenation by purging with an inert gas is required, that is, the problem of foam formation and frothing, which makes such degassing problematic and cumbersome. Several approaches have been employed to overcome this difficulty. For instance, a simple gas bubbling system for removal of dissolved oxygen in surfactant and micellar solutions has been described.[834] This cell allows a continuous, rapid flow of a purge gas through such solutions without loss of fluid in spite of severe foaming. Using this cell, the oxygen concentration was reduced to a negligible value ($<10^{-5}$ M) in about 13 min.[834] A very similar cell system has also been described by other workers to minimize foam losses during deaeration.[835]

Alternatively, *in situ* chemical deoxygenation can be employed.[836] For instance, sulfite ion has been utilized as an oxygen scavenger in anionic micellar[836] or CD[837] solutions. This method is based on the redox reaction shown in Equation (9):

$$O_2(g) + 2SO_3^{2-}(aq) \Longleftrightarrow 2SO_4^{2-}(aq) \qquad (9)$$

This approach is rapid (requiring about 12–15-min reaction time), convenient, precise, and superior to the solution nitrogen purging technique.[836] In particular, this deoxygenation procedure has been employed in the context of micelle- (or CD)-stabilized room-temperature phosphorescence[836,837] (*see* **Phosphorescence Measurements, Applications of**) as well as in applications of terbium-sensitized luminescence applications.[783] However, it has been cautioned that addition of sulfite to some micelle systems, such as SDS containing thallium(I), can result in the formation of a metal–sulfite complex which absorbs radiation below 275 nm.[838] Therefore, in applications involving the determination of metal ions in which this deoxygenation scheme is employed, experiments should first be conducted to ensure that such a metal–sulfite complex does not form or, if formed, that the resulting complex does not absorb appreciably at the required fluorescence excitation wavelength.

Another effective means of degassing solutions of organized media is through multiple freeze–pump–thaw cycles on a high-vacuum line to avoid the effects of traces of oxygen.[839,840] However, such vacuum degassing is not very convenient and requires a vacuum line system, etc. In addition, vacuum degassing micelle solutions are not significantly better than nitrogen purging as a means of deoxygenation as gauged from fluorescence probe studies.[840] However, there are some reports that note that the nitrogen bubbling technique for removal of oxygen from solutions does not eliminate all traces of the $O_2(g)$, with an estimated 2 μM residual oxygen gas still present following such purging.[502,686]

Lastly, the use of an automated sample deoxygenation system might also be applicable to solutions containing some of the organized assembly systems.[840] Two reports provide a nice survey of current methods employed for deoxygenation of solutions along with their advantages, limitations, and analytical applications.[841,842]

It should be noted that freshly prepared aqueous solutions of some organic solutes in the absence and presence of CDs appear to be unstable when the solutions are exposed to the atmosphere and/or bubbled by air or nitrogen gas.[843] Repeated bubbling–freezing–thawing cycles enhance the effect.

The preparation of required concentrated stock solutions of analytes in aqueous organized assembly solutions is sometimes problematic owing to extremely low solute solubilities or slow dissolution rates.[363,844] In many such cases, the following general protocol has been employed: (i) initially prepare a concentrated analyte stock solution in a water-miscible organic solvent (alcohol, acetone, tetrahydrofuran, etc.) in which it is soluble, (ii) then add a small aliquot of this concentrated solution to the aqueous organized assembly solution (typically strive to keep the percentage of the organic cosolvent under 0.5% (v/v)), (iii) next, purge the resulting organized assembly solution with nitrogen or argon in order to remove/displace the small amount of organic solvent present, and (iv) lastly, add an appropriate amount of water to this solution to compensate for evaporation.[194,363,844] Alternatively, the purge step can be skipped provided all analytical fluorescence measurements are conducted on standard and unknown solutions that contain the same amount of organic cosolvent. While this procedure is successful in most instances, for some solutes it results in the

formation of microcrystals of the analyte, and these can be a source of artifacts, since their resulting solutions can scatter light and/or give rise to strong excimer emission.[194,844]

Some of the preparation recipes for formation of SUV systems require the presence of small amounts of an organic solvent (typically chloroform, which is a potential fluorescence quencher as well). Thus, nitrogen purging is sometimes also utilized to remove traces of such organic solvents.[511,515]

Recall that the presence of organic cosolvents can preclude (or alter) surfactant micelle formation. Thus, if such cosolvents are utilized in the preparation of solutions, they should be present at low concentrations (final percentage <1.0% (v/v)).[385] Such a low organic cosolvent concentration serves to minimize the perturbation to the surfactant aggregate structure. As previously noted, bile salt surfactant systems can tolerate greater amounts of such organic additives than the classic surfactant micelle-forming systems.

As noted, when manipulating (pipetting, shaking to mix, etc.) aqueous surfactant micelle solutions, bubble (foam) formation can cause difficulties (such as when trying to add water to dilute to the mark of volumetric glassware). It has been noted that when working with such surfactant solutions in the laboratory, they can be freed of bubbles by placing the container in an ultrasonic bath filled with water. Apparently, after only a few seconds of exposure to ultrasound, clear, bubble-free solutions are obtained.[845] In one reported application, 15 min of this type of ultrasonic ''stirring'' was employed to remove air bubbles.[670]

As has been cautioned in the literature by others, care should be exercised with respect to the type of electrodes employed and the meaning of any pH measurements made in micellar- (or vesicle)-containing solutions.[846]

The interested reader is referred to any number of published applications for more detailed experimental protocols and the different experimental variables that can impact the fluorescence signal when utilizing different organized assemblies in fluorescence methods.[711,847–878]

5 CONCLUSIONS

In contrast to the situation in the mid-1980s, when the use of organized assemblies in analytical fluorimetry was still largely unexplored,[20] this is now an established practice in chemical analysis. The reported advantages in terms of the ability to control solubility, reactivity, sensitivity, and, to a lesser degree, selectivity by the judicious choice and use of an organized assembly system is the reason for the popularity and success of organized assembly–enhanced fluorescence measurements. Future research should be directed toward increased use of these systems in rate/kinetic methods of analysis, development of functionalized ordered media which target a specific analyte of interest, and different means by which to immobilize the surfactant micelle/vesicle systems. Development of such materials that mimic their properties will serve to extend the scope of possible applications. Some trends in this field have been noted in a review article.[879] In particular, the utilization of ''designer'' surfactant and CD media for application as specific fluorescent sensors is becoming very popular.[164,165,173,880–882] The use of surfactant-mediated CP extraction (for preconcentration of the analyte) combined with fluorescence enhancement should lead to the development of ultratrace methods. An overlooked but very beneficial application concerns the utilization of these aqueous organized media to enhance sample preservation and long-term storage of environmental and biological samples, in the context of not only fluorescence measurements but chemical analysis in general.

ACKNOWLEDGMENTS

This chapter is dedicated to late Prof. Janos H. Fendler for his pioneering research and development of the general field of organized assemblies and membrane mimetic chemistry. We thank our coworkers, whose names appear in the references listed, for their dedicated and enthusiastic contributions to our work cited in this review. Many thanks are due to Prof. Frank H. Quina (Instituto de Quimica, Universidad de Sao Paulo, Brazil) for his careful reading of the proofs and helpful comments in the preparation of this article. In addition, we thank an anonymous referee for helpful comments regarding the improvement of this manuscript as well as for providing additional useful citations. Acknowledgment is also made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, Pharmatec, Inc. (Alachua, FL) and Wake Forest University (through a Research and Publication Fund Grant) for providing financial support for our own work in this research area. This article was written while one of us (W. L. Hinze) was supported by a Wake Forest University Reynolds Research Leave. Additionally, N. Memon and A. Balouch gratefully acknowledge the Higher Education Commission of Pakistan and NCEAC (University of Sindh, Jamshoro, Pakistan) for their support of this work and granting of a study leave during their time at Wake Forest University.

ABBREVIATIONS AND ACRONYMS

ANS	8-Anilino-1-naphthalenesulfonate
AOD	Acridine orange-10-dodecyl Bromide
ATP	Adenosine Triphosphate
BA	Benzoic Acid

TFTD	1,1,1-Trifluoro-2,4-tridecanedione
TLC	Thin-layer Chromatography
TNS	2-*p*-Toluidinonaphthalene-6-sulfonate
TOPO	Trioctylphosphine Oxide
TRCB	3,4,4′-Trichlorobiphenyl
TTA	Thenoyltrifluoroacetone
TTCB	3,3′, 4, 4′-Tetrachlorobiphenyl
TTCDF	2,3,7,8-Tetrachlorodibenzofuran
UV/vis	Ultraviolet/visible

Over the years, the emissive characteristics (spectral, temporal, and polarization) of fluorophores have been widely used to probe the local environments of fluorescent centers. Fluorescence lifetime and rotational reorientation time measurements, in particular, offer a means to elucidate subtle features when examining, for example, complex systems involving environmental heterogeneity, energy transfer, quenching pathways, or excited state reactions. Further, because fluorescence occurs on the nanosecond (10^{-9} s) timescale, competing or perturbing kinetic processes like collisional quenching, solvent relaxation, energy transfer, and rotational reorientation can affect the fluorescence. Thus, a carefully chosen fluorophore can serve as an internal nanosecond or faster stopwatch of environmental fluctuations.

This article is divided into a brief introduction, a short discussion on instrumentation, and several sections on various applications of excited state fluorescence measurements.

1 INTRODUCTION

During the last few decades, fluorescence spectroscopy has developed into an important and widely used technique in the biological, chemical, and physical sciences. Multidimensional in nature, fluorescence is characterized by several parameters, most notably the excitation and emission wavelengths, the steady state polarization or anisotropy, the excited state lifetime, and the rotational reorientation time.[1] Of these, the latter two reflect the time course of the emission process; therefore, it is often of interest to determine such time-dependent emission from samples. This arises because the fluorescence anisotropy and/or intensity decay kinetics are usually characteristic of the system under investigation.[1–16] In condensed phase systems, these two processes typically occur in 10^{-8}–10^{-13} s. As a result, any process which occurs on a similar timescale can potentially perturb the fluorescence. For example, phenomena like collisional quenching, energy transfer, solvent relaxation, and rotational reorientation all occur on the fluorescence timescale. Hence an excited state fluorophore can be used to report on its local environment as well as temporal changes in the environment. Consequently, this information provides insight into important processes occurring on the nanosecond and subnanosecond timescale. For example, the presence of two fluorescent tryptophan residues within a protein, each of which resides in a distinct physicochemical environment, may manifest itself in the recovery of two apparent decay rates, as has been observed by Ross et al.[2] for liver alcohol dehydrogenase. Alternatively, the dynamical behavior of proteins can result in intrinsically multiexponential fluorescence anisotropy decays, where the more rapidly relaxing components reflect the amino acid residue segmental motions.[3] Further, many aspects of the changes at the molecular level such as energy transfer,[4] conformational distributions,[5] and transient effects in collisional quenching[6,7] display complex emission kinetics that are accessible from dynamical measurements.

In principle, resolution of the time-dependent decays of anisotropy and/or intensity can be equivalently accomplished using either time- or frequency-domain measurements.[8–16] In the time domain (impulse response approach), the temporal emission from the sample

following pulsed excitation (ideally a Dirac δ-function) is measured using detectors with high temporal resolution (e.g. streak cameras) or time-sampling circuitry (e.g. time-correlated single photon counting approach). In the frequency domain (harmonic response approach), the emission phase angle lag and modulation attenuation relative to the sinusoidally modulated incident light are measured.

The first analytical paper on time-resolved spectroscopy, published in 1957 by Keirs, Britt, and Wentworth, was based on measuring phosphorescence lifetimes (see O'Connor and Phillips[10]). Some 42 years later, the improvements in optical technology and continued advances in digital electronics and computing power have lead us to the era of ultrafast spectroscopy.[16] Before we discuss these methods that are actually used to measure the anisotropy and/or intensity decay kinetics, it is instructive to look at the general expressions describing fluorescence intensity and anisotropy decay kinetics.

For a system containing n noninteracting fluorescence species (components), following excitation with an optically short Dirac δ-function, the time-dependent emission decay can be described by a multiexponential series of the form, Equation (1):[8–15]

$$I(t) = \sum_{i=1}^{n} \alpha_i \exp\left(-\frac{t}{\tau_i}\right. \tag{1}$$

This expression is strictly true for discrete lifetime components. Here, α_i is a pre-exponential factor that represents the fractional contribution of the ith component, possessing excited state lifetime τ_i, to the total time-resolved intensity decay. The fractional contribution to the total intensity decay (f_i) of each species is then given by Equation (2):

$$f_i = \frac{\alpha_i \tau_i}{\sum_{i=1}^{n} \alpha_i \tau_i} \tag{2}$$

Of course, nonexponential or complex exponential decays are often observed in what are assumed to be simple systems because of competing processes (e.g. solvent relaxation, energy migration) or inherent heterogeneity. In cases where single or multiple fluorophores are located simultaneously in or interconverting between an ensemble of distinct environments, a distribution of excited state lifetimes reflecting the environmental distributions would be expected a priori. From Equations (1) and (2) it can be shown that:

$$I(t) = \sum_{i=1}^{n} f_i \tau_i^{-1} \exp\left(-\frac{t}{\tau_i}\right. \tag{3}$$

For the limiting case where the number of emitting centers is large, Equation (3) can be expressed as an integral of the form, Equation (4):

$$I(t) = \int_0^\infty f(\tau)\tau^{-1} \exp\left(-\frac{t}{\tau}\right. \mathrm{d}\tau \tag{4}$$

Most approaches to the study of excited state lifetime distributions assume that $f(\tau)$ is given by one of several continuous distribution functions, Equations (5–7):

$$\text{uniform:} \quad f(\tau) = A \quad \text{from } (\tau - W/2) \text{ to } (\tau + W/2) \tag{5}$$
$$f(\tau) = 0 \quad \text{at all other values}$$

or

$$\text{Gaussian:} \quad f(\tau) = A\left\{\frac{\exp[-(\tau - \tau')^2/2\sigma^2]}{\sigma\sqrt{2\pi}}\right\} \tag{6}$$

or

$$\text{Lorentzian:} \quad f(\tau) = \frac{A}{\{1 + [(\tau - \tau')/(W/2)]^2\}} \tag{7}$$

where τ' is the central or mean lifetime value, σ is the standard deviation of the Gaussian distribution, W is the full width at half-maximum (fwhm) for the Lorentzian and uniform distributions, τ is the lifetime, and A is an amplitude constant determined from the normalization condition, Equation (8):

$$f(\tau)\,\mathrm{d}\tau = 1 \tag{8}$$

In a time-resolved anisotropy decay experiment, the sample is excited with a brief pulse of vertically polarized light and the time dependence of the parallel $[I_\parallel(t)]$ and perpendicular $[I_\perp(t)]$ components of the fluorescence provide the time-resolved decay of anisotropy $r(t)$, Equation (9):

$$r(t) = \frac{I_\parallel(t) - I_\perp(t)}{I_\parallel(t) + 2I(t)_\perp} \tag{9}$$

For a simple isotropic rotor, $r(t)$ decays with a single rotational reorientation time, ϕ, Equation (10):

$$r(t) = r_0 \exp\left(-\frac{t}{\phi}\right. \tag{10}$$

where r_0 is the so-called limiting anisotropy measured in the absence of any rotational reorientation. For more complicated systems, $r(t)$ may take the form of a string of exponentials, Equation (11):

$$r(t) = r_0 \sum_{i=1}^{n} \beta_i \exp\left(-\frac{t}{\phi_i}\right. \tag{11}$$

where β_i and ϕ_i are the fractional contribution of the total decay of anisotropy and the rotational correlation time

attributed to the *i*th apparent rotational reorientation event, respectively.

There are several methods used to obtain excited state intensity decay $I(t)$ and/or anisotropy decay $r(t)$. Some of the methods will be discussed here briefly. For a more elaborate description, the reader is directed to the specific literature references provided.

1.1 Time Correlated Single Photon Counting

Time correlated single photon counting (TCSPC)[10–12] relies on the concept that the probability distribution for emission of a single photon after an excitation event yields the actual intensity versus time distribution of all the photons emitted as a result of the excitation. By statistically sampling the single photon emission following a large number of excitation events, the experiment constructs this probability distribution.[10]

Figure 1 Typical TCSPC excited state intensity decay data for dilute 1-ethylpyrene dissolved in liquid toluene. The best fits for mono- (- - - -) and bi-exponential (———) decay functions are shown through the experimental data points (a). $\tau_1 = 170\,\text{ns}$ ($f_1 = 0.92$), $\tau_2 = 1.68\,\text{ns}$ ($f_2 = 0.08$), $\chi^2_{\text{single}} = 9.68$, $\chi^2_{\text{double}} = 1.73$. The recovered residuals for single (○) and double (●) exponential fits are provided in (b).

The TCSPC technique was first used by Bollinger and Thomas in 1961 (see O'Connor and Phillips[10]). To measure the luminescence decay characteristics of scintillators excited by α-, β-, and γ-radiation. Koechlin (see O'Connor and Phillips[10]), in the same year, used TCSPC to determine the shapes of scintillator emission curves with resolution in the nanosecond range. By way of illustration, Figure 1(a) shows a TCSPC fluorescence decay curve for a dilute solution of 1-ethylpyrene dissolved in liquid toluene. From the fits and corresponding residuals for single and double exponential decay laws, associated χ^2 values and residuals (Figure 1b), it is clear that a double exponential decay law is required to describe the overall decay kinetics adequately.

In TCSPC, as the excited state intensity decay kinetics approach the timescale of the so-called instrument response function (Figure 1a), the discrimination between the two becomes more and more critical to recovering accurate decay constants. The typical way to recover the decay parameters from the decay trace and the instrument response function is to solve the convolution integral, Equation (12):

$$F(t) = \int_0^t P(t')I(t-t')\,\mathrm{d}t' \tag{12}$$

In this expression, $P(t')$ is the instrumental response, $I(t-t')$ is the impulse response from the sample which describes the kinetic model, and $F(t)$ represents the decay curve. If the measured excited state decay is represented by $Y(t)$, the goodness of fit (χ^2) between $F(t)$ and $Y(t)$ can be optimized by iterating the parameters in $I(t)$ via assessing using normalized chi-squared values (χ^2) where, Equation (13):

$$\chi^2 = \frac{1}{(N-n)} \sum_{i=1}^{N} \frac{(Y_i - F_i)^2}{Y_i} \tag{13}$$

for N data points and n fitting parameters. For a good fit, χ^2 should be "close to unity" (see Figure 1).[10]

1.2 Multifrequency Phase and Modulation Fluorometry

In the frequency domain, the sample under study is excited with sinusoidally, amplitude-modulated light.[13–15] Typically, these frequencies span the mega- to gigahertz regions and have been generated by using acousto-optical, electro-optical or piezo-optical devices, continuous wave (CW) or mode-locked lasers, and synchrotron sources.[13] The resulting time-dependent fluorescence is slave to the frequency of the excitation waveform, but is phase shifted (θ) and amplitude demodulated (M) to an extent dependent on the fluorescence lifetime(s) inherent to the sample. For any

decay process the calculated (denoted by subscript c) values of θ and M are given by[13] Equations (14) and (15)

$$\theta_c(w) = \tan^{-1} \frac{S(w)}{C(w)} \tag{14}$$

$$M_c(w) = \{S(w)\}^2 + \{C(w)\}^2 \,^{1/2} \tag{15}$$

where w is the angular frequency and, for a single exponential decay, Equations (16) and (17):

$$\frac{S(w)}{C(w)} = w\tau \tag{16}$$

and

$$[S(w)]^2 + [C(w)]^2 = \left(1 + w^2\tau^2\right)^{-1} \tag{17}$$

For a general decay model expressed by Equation (1), the frequency-dependent sine $S(w)$ and cosine $C(w)$ Fourier transforms are given by Equations (18) and (19):

$$S(w) = \int_0^\infty I(t) \sin wt \, dt \tag{18}$$

$$C(w) = \int_0^\infty I(t) \cos wt \, dt \tag{19}$$

The decay times are recovered by experimentally measuring $\theta_m(w)$, the frequency-dependent phase shift, and $M_m(w)$, the frequency-dependent modulation, values while probing the sample at several angular modulation frequencies ($w = 2\pi f$, where f is the linear modulation frequency in hertz), followed by analysis using nonlinear least squares fitting algorithms. In this approach, the sum of the squared differences between the calculated ($\theta_c(w)$ and $M_c(w)$) and measured ($\theta_m(w)$ and $M_m(w)$) values are minimized using the χ^2 as a measure of the goodness-of-fit, Equation (20):

$$\chi^2 = \frac{1}{D}\sum_w \frac{(\theta_m(w) - \theta_c(w))}{v_\theta^2}^2 + \frac{1}{D}\sum_w \frac{(M_m(w) - M_c(w))}{v_M^2}^2 \tag{20}$$

Here, v_θ and v_M are the variances in the measured phase angle and demodulation, respectively, and D is the number of degrees of freedom. When v_θ and v_M reflect accurately the uncertainties in the θ (phase angle) and M (demodulation) experimental measurements, the fit quality is judged by the closeness of χ^2 to unity, the randomness of the phase angle and demodulation residuals about zero, and the physical significance of the model. Figure 2 shows a typical phase-modulation data set for calcium green dissolved in pH 7.2 phosphate saline buffer (10 mM in Ca(II)). In Figure 2(a),

Figure 2 Typical MHF (multiharmonic Fourier transform) phase-modulation data (●) for calcium green dissolved in buffer with 10 mM Ca(II) at 40 °C (a). The best single (- - - -) and double (———) exponential fits to the data are shown as well as the associated χ^2 values: $\chi^2_{single} = 98$, $\chi^2_{double} = 0.86$, $\tau_1 = 3.70$ ns ($f_1 = 0.86$), $\tau_2 = 0.70$ ns ($f_2 = 0.14$). Frequency-dependent phase (b) and modulation (c) residuals are also provided for single (●) and double (○) exponential fits.

the points denote the experimental data and the fit to a single and double exponential decay law are shown. The fit of these data to a double exponential decay law is far superior to the fit to a single exponential decay law. Frequency-dependent phase and demodulation residuals (Figures 2b and 2c) demonstrate the difference between the fit to a single and double exponential decay law.

1.3 Pump–Probe Spectroscopy

For measurement of very fast relaxation processes which demand a time resolution below 10^{-10} s, most detectors are simply not fast enough (with the notable exception of streak cameras which, besides being very expensive, are restricted in their application by lower sensitivity, lower dynamic range, and the necessity of careful calibration and alignment). In this case, the pump–probe[16,17] technique offers the best alternative. In this technique, the species under investigation are excited by a fast laser pulse (i.e. pump) (Figure 3a). A second laser pulse, with a variable delay time Δt relative to the pump pulse, probes the time evolution of the excited state population density (Figure 3b). The signal intensity is proportional to the fluorescence intensity, provided that the probe pulse is not overly intense. The probe pulse arrival time is controlled by physically changing the probe beam optical path (Figure 3c). Incremental variation in the arrival time (i.e. probe pulse delay) allows the temporal decay function to be constructed.

In pump–probe spectroscopy, the time resolution is limited by the fundamental laser pulse widths and not by the detector intrinsic response time. The ability to generate ultrafast laser pulses thus allows pump–probe spectroscopy to be performed on a subpicosecond

Figure 3 (a) In pump–probe spectroscopy, molecules under investigation are excited by a fast laser pulse on the $|0\rangle \rightarrow |1\rangle$ transition. (b) A probe pulse with a variable time delay Δt against the pump pulse probes the time evolution of the population density $N_1(t)$. (c) Schematic of a simplified instrumental set-up used in pump–probe spectroscopy for the measurement of an ultrafast relaxation processes. (Adapted from Demtroder.)[17]

timescale. Moreover, a broader range of applications is opened up by using two independently tunable ultrafast lasers that use the same pump laser to synchronize the pump and probe pulses.

1.4 Up-conversion

Another method that is well suited for the determination of excited state fluorescence anisotropy and intensity decay kinetics is termed up-conversion. This methodology subpicosecond fluorescence anisotropy and intensity decays to be determined.[16] Up-conversion refers to the nonlinear phenomenon of sum-frequency generation within anisotropic crystals. Figure 4 shows a general schematic of an up-conversion instrument. This method relies upon the generation of a signal of frequency w_3, which is the sum frequency for fluorescence w_2 and the exciting laser frequency w_1. In this case, w_3 can be distinguished spatially as well as by its frequency. When used to measure fluorescence decays, up-conversion offers several advantages over TCSPC. As well as vastly improved time resolution, it permits detection of fluorescence in the far red and infrared without the use of red-sensitive detectors. For example, fluorescence at 900 nm can be mixed with laser light at 600 nm to generate a sum frequency at 360 nm. The primary disadvantage, however, is that up-conversion of fluorescence toward the blue end of the spectrum is more difficult owing to the absence of efficient mixing crystals operating in the far ultraviolet. The ultimate time resolution of an up-conversion experiment is set by the excitation pulse duration.

Figure 4 Simplified block diagram of the instrumental set-up used for an up-conversion experiment. A fraction of the laser output is used to excite the sample while the remainder is variably delayed for use in the up-conversion process. Fluorescence is collected via an off-axis curved mirror and directed into the up-conversion crystal. The resulting ultraviolet output intensity of the crystal is proportional to the intensity of the fluorescence at a particular delay time photomultiplier tube (PMT). (Adapted from Wirth.)[16]

2 INSTRUMENTATION

Since the early 1980s, significant advances have been made in instrumentation for time domain and frequency domain fluorescence spectroscopy. With present time domain instrumentation and optical up-shifting techniques, femtosecond processes are now being routinely explored.

2.1 Time Domain[10,12]

The additional specialized equipment needed to implement TCSPC includes a pulsed light source such as a laser or spark discharge, a fast response detector, and a time-to-amplitude convertor (TAC). Figure 5 shows a simplified schematic of a TCSPC instrument. It is important to mention here that several additional instrumental refinements are required but are of secondary importance and beyond the scope of this article. The reader is directed to O'Connor and Phillips[10] for a more detailed discussion. The TAC, the most critical device in the time correlation process, measures the elapsed time between the initial rise in intensity of the pulsed light source and the detection of an emitted photon.[12] In operation, an electrical pulse is generated at a time exactly correlated with the time of generation of the optical pulse by the trigger (e.g. a PMT output, an antenna pick-up, or a logical synchronized pulse). After receiving the trigger pulse, the TAC initiates the charging of a capacitor plate which is routed to the TAC start input via a discriminator. While the same optical pulse that triggered the TAC excites the fluorescent sample, an aperture is adjusted on the emission arm so that only one photon is detected for every 100–200 excitation events. The signal resulting from this photon stops the charging ramp in the TAC, which transmits a pulse. The amplitude of this pulse is proportional to the charge in the capacitor, and hence to the time difference between the start and stop pulses. The TAC output pulse is given a numerical value within the analog-to-digital converter (ADC) and a count is stored in the data storage device (a multichannel pulse height analyzer; MCPHA) in an address corresponding to

Figure 5 Simplified block diagram of a conventional TCSPC apparatus (Adapted from O'Connor and Phillips[10] and Cline-Love and Shaver.[12]) Please refer to the text for further experimental description. MCA/PC, Multichannel Analyzer Personal Computer.

that number. Excitation and data storage are repeated in this way until the histogram of number of counts against address number in the storage device represents, to some required precision, the decay curve of the sample.[10] A typical TCSPC trace from a flash lamp-based instrument is illustrated in Figure 1. With current pulsed laser sources and microchannel plate PMT detectors, it is possible to determine excited state processes routinely on the low picosecond timescale.

2.2 Frequency Domain

In the frequency domain,[13] the latest instrumentation has made it possible to measure picosecond decay kinetics routinely. These advances have been made possible by the use of excitation sources with large bandwidths and detectors with high gain and wide bandwidths.[13]

A simplified schematic for a multifrequency, cross-correlation[14] phase and modulation instrument that is capable of parallel acquisition of phase and modulation data is presented in Figure 6. In a frequency domain measurement, the excitation source can be an intensity modulated CW light source or a high repetition rate pulsed laser. The choice of source usually depends on the required wavelengths, the power level needed, and the experience and other constraints of the researchers. Laser sources can be easily modulated using one of several modulation schemes.[13] In most modern frequency domain instruments, the harmonic content of pulsed lasers produces modulation to many gigahertz such that the bandwidth of frequency domain instruments is now limited only by the detector response time.[14]

To illustrate the range of light sources used in phase modulation fluorescence, we have selected two extreme examples. Sipior et al.[18] demonstrated the use of an inexpensive, commercially available blue light emitting diode (LED) to produce amplitude-modulated near-ultraviolet light as a source for nanosecond phase-modulation fluorescence lifetime measurements. The most recent advance in multifrequency phase and modulation fluorescence has been the development of instrumentation for the parallel acquisition of phase and modulation data.[19–21] In this design, the phase and modulation across the entire

Figure 6 Simplified schematic of a multiharmonic Fourier phase and modulation fluorometer. The dashed lines denote optical paths while the solid lines indicate electrical connections. Abbreviations represent power amplifiers (A1, A2); PMT detectors (PMT1, PMT2); and harmonic comb generators (HCG1, HCG2). (Adapted from Bright et al.)[13]

frequency spectrum can be collected simultaneously and experiments that took about 1 h can now be completed in <10 s.[13] More recently, a parallel multiharmonic frequency domain fluorometer was designed by Bright et al. that can rapidly measure excited state fluorescence anisotropy and intensity decay kinetics following one-, two-, or three-photon excitation.[21]

3 SOLVATION DYNAMICS

The time evolution of an emission spectrum provides insight into how the local solvent environment affects the emission process. Time-resolved fluorescence experiments have been used to study the energetics of the solvation process, because fluorophores provide an internal clock from which to observe processes occurring on the fluorescence timescale. That is, if a secondary process (a reaction) occurs on the same timescale as fluorescence, it can often perturb the fluorescence intensity decay kinetics. Thus, the kinetics of the secondary process can be inferred via its impact on the time-resolved fluorescence decay. Bakshiev, Mazurenko, and co-workers pioneered the use of time-resolved fluorescence for transient solvation studies (see Ravichandran and Bagchi,[22] Simon,[23] Nagarajan et al.[24]). Initial experiments in this field were limited by the nanosecond time resolution of early instrumentation. As a consequence, the majority of these experiments were carried out in viscous solvents, at relatively low temperatures, and/or on samples dissolved in nonpolar (noninteracting) solvents modified (perturbed) by the addition of small amounts (<1% by volume) of a polar cosolvent. In this way, these investigators were able to bring the solvation process ''down to'' the time regime of their instrumentation. Recent advances in instrumentation have now made it possible to perform studies in neat liquid solvents like acetonitrile, water, methanol, and other alcohols. Subpicosecond spectroscopy has also been used by to study the microscopic solvation dynamics of less viscous liquids.[24]

In order to understand the time evolution of spectral shifts due to universal excited solute–solvent interactions, it is useful to invoke the Franck–Condon principle. Upon excitation, a molecule will retain the particular solvent configuration which is favored in the ground state, because solvent molecules cannot reorient during the excitation event. If the excited state, formed directly by light absorption or indirectly via a fast subnanosecond reaction, has a new dipole moment, and if the solvent relaxation time is less than the excited state fluorescence lifetime, the solvent dielectric medium surrounding the fluorophore will be polarized differently from in the ground state. Thus, a new reaction field developed by this orientation strain is created by the fluorophore and the solvent molecules surrounding this new dipole will relax and reorient to accommodate the change in dipole moment of the excited fluorophore until equilibrium has been restored. When this solvent relaxation time becomes comparable to the excited state fluorescence lifetime, time-resolved spectral shifts in addition to electronic relaxation will be observable.

Pierce and Boxer reported the time-dependent solvation for a fluorophore within a protein by following the time-dependent fluorescence Stokes shift.[25] Specifically, these authors reported on the complex formed between sperm whale apomyoglobin and 2′-(*N*,*N*-dimethylamino)-6-naphthoyl-4-*trans*-cyclohexanoic acid at temperatures between 243 and 298 K. The decay of the mean emission energy was not single exponential and there were decay components spanning and probably exceeding their experimentally observable time window (20 ps to 20 ns). These results suggested that either the activation energies of the rate-limiting motions in the relaxation are dependent on substrate conformation, or that different types of protein motion with different characteristic frequencies participate in the relaxation.

Mertz et al.,[26] while investigating how the Stokes shift of proflavin was affected by solvent dipolarity, reported that the dependence of the solvent reorganization free energy on the solvent dielectric properties can be explained if two effects are taken into account. The first effect is the distortion of dielectric properties of a uniform solvent by embedding a bulk solute molecule in the solvent. The second effect is the influence of the solvent dipolarity on the electronic density redistribution upon an electronic transition event. These particular data also supported the notion that the commonly adapted equation for Stokes shift that establishes equality between Stokes shift and the doubled reorganization energy is not rigorously true, in general. Indeed, these authors showed that the measured experimental data are consistent with a more rigorous and appropriate approximation of Stokes shift that takes into account the quantum nature of the solute local modes.

Rempel et al., using temperature-dependent time-resolved Stokes shift measurements of Coumarin 153 (C153), explored the solvation dynamics in binary mixtures of alcohols and alkanes and concluded that, depending upon the actual alcohol concentration, the Stokes shift takes place on a timescale ranging from 300 ps to several nanoseconds.[27] These characteristic times were two orders of magnitude longer than the relaxation times typically observed for C153 dissolved in neat alcohols. This effect was attributed to solvent/cosolvent rotational reorientation. These authors also observed that the temporal behavior of the Stokes shift was monoexponential and the time constants depended

linearly on the alkane viscosity. They concluded that their data strongly support a diffusion-controlled process of solvation in these mixtures.

Glasbeek et al. used fluorescence up-conversion of 1-phenyl-4-[(4-cyano-1-naphthyl)methylene]piperidine (PCNMP) in its lowest excited charge transfer state when dissolved in a series of solvents.[28] These experiments were performed at room temperature with 300 fs time resolution. The observed Stokes shift was attributed to the solvent response to the large photoinduced PCNMP dipole moment ($\sim$30 D). The solvation dynamics were reported to be governed by the rotational diffusional motions of the ethereal solvent molecules.

Solvent relaxation of indole dissolved in polar protic solvents and analysis of the fluorescence lifetime distributions and time-dependent spectral shifts were reported by Demchenko et al.[29] These authors used the maximum entropy method (MEM) and obtained relatively narrow peaks for the fluorescence lifetime distribution, which originate first from the main emission decay component and second from additional short components which are due to spectral kinetic processes. These short-lived components were extremely sensitive to temperature. The authors were also able to use time-resolved emission spectroscopy to reveal relaxation times over the same range recovered for the observed lifetime distributions. Results of excited state stabilization energy measurements, combined with time-dependent spectral shifts, were found to be consistent with a mechanism of general dielectric solvent relaxation rather than formation of binary excited state complexes in the time range studied.

Wendt and Richert recently reported the Stokes shift and Stokes shift dynamics for naphthalene (change in dipole moment upon excitation $\sim$0 D) and quinoxaline ($\sim$1.3 D) dissolved in *n*-propanol and other glass-forming solvents.[30] The time dependence of the Stokes shift for naphthalene was reported governed by the structural (or shear stress) relaxation time of *n*-propanol, without any signature from the strong dielectric relaxation. For this solvent, structural and dipolar contributions can be distinguished because the timescale for dipolar reorientation is 25-fold slower than the shear stress relaxation time. These authors concluded that the naphthalene solvation reflects excitation-induced changes in the van der Waals interactions, which makes it an ideal probe for assessing shear stress or mechanical relaxations on microscopic spatial scales near the glass transition temperature (T_g).

In a recent review, Fleming and Cho present experimental and theoretical studies of polar solvation dynamics and spectral line broadening.[31] Spectral broadening, arising from interactions with the environment in the time domain (the dephasing timescale), is an effect arising from the averaging over the ensemble that is intrinsic to linear spectroscopic measurements. An important feature of time-resolved fluorescence and ultrafast spectroscopy is that they can be used to undo the ensemble average and allow molecular dynamics to be observed directly in condensed phases.

Bright et al., during their investigation of the behavior of acrylodan-labeled bovine serum albumin and acrylodan-labeled human serum albumins (BSA-Ac and HSA-Acs) sequestered within a tetramethylorthosilane-derived xerogel, used the dipolar relaxation kinetics to quantify the relaxation of the Ac fluorophore cybotactic region following optical excitation.[32] These results suggested that there was a substantial amount of nanosecond and subnanosecond dipolar relaxation within the local environment surrounding cysteine-34 in both proteins, even when they were sequestered within ''dry'' xerogels. The solvation dynamics of BSA-Ac and HSA-Ac differ with the initial xerogel preparation, suggesting that the slight differences in amino acid sequences do indeed affect the cybotactic region surrounding the Ac residues within these proteins.

4 APPLICATIONS IN BIOCHEMISTRY AND BIOPHYSICS

Time-resolved fluorimetry is probably second only to NMR (nuclear magnetic resonance) in its ability to solve diverse and significant problems in the biochemical and biophysical sciences.[33,34] In particular cases, stemming from signal inadequacy, sample scarcity or special constraints, fluorescence spectroscopy is uniquely suited to tackle such problems. Areas of recent study include immunoassay, enzymatics, protein–ligand binding, biosensor development and diagnostics, denaturation kinetics, nucleic acid determination, oligonucleotide hybridization, and protein self-association.

Time-resolved fluorescence is an invaluable tool for studying processes involving primary energy and charge transfer in photosynthesis and photosensitization. For example, our understanding of photosynthesis was largely achieved by performing dynamic fluorescence experiments over several timescales.[33,35] As a result of such efforts, a contemporary view of photosynthetic kinetics has been realized. Although many aspects of the process are still veiled in mystery, the most widely accepted model of the photosynthetic membrane includes four features essential to the complex electron-transfer mechanics: (1) photosystem I (PS I) and II (PS II) reaction centers which operate in series to effect charge separation, (2) a pigment-binding protein light-harvesting assembly, (3) a membrane to isolate products physically, and (4) requisite redox and assembly enzymes.

In photosynthetic pathways, appropriately energetic trapped photons promote electrons into higher energy excited states. Electrons in these elevated states, however, tend to decay to ground singlet states on a nanosecond timescale, wasting potential energy in the form of light and heat. In order to prevent this scenario, chromophores must donate excited electrons to quinone acceptors faster than the rate of excited state decay (i.e. recombination). The resulting charge separation at the reaction center chemically preserves some of the incident photon energy in the form of a stable transmembrane electrical potential.

The role of protein–chromophore interactions in the mechanism of energy transfer was probed by de Paula et al.[35] by using time-resolved fluorescence to study chlorophyll a bound to the 47 kDa antenna protein (CP47) of spinach PS II. These authors used picosecond fluorescence spectroscopy to characterize CP47 and distinguish between functional (intact or perturbed) and nonfunctional (denatured) centers in various formulations. The structural heterogeneity (e.g. donor–acceptor distance, vibronic coupling) gives rise to multiple recombination rates which are manifest in the multiexponential decays observed.

The field of photosensitization is another expanding area of application for dynamic fluorimetry. For example, photodynamic therapy (PDT) involves the administration and photoactivation of a suitable photosensitizing agent as a medical means of treating solid, localized tumors.[33,36] In PDT, it is generally accepted that energy transfer takes place from a luminophore excited triplet state to ground state triplet oxygen to produce the cytotoxic singlet oxygen. Although numerous dyes such as the acridines, coumarins, and porphyrins have been studied for their tumor-localizing properties and effectiveness as potential PDT agents, research has increasingly centered on hematoporphyrin derivatives and Photofrin II® (a proprietary drug marketed by Quadra Logic Technologies Inc.). Unfortunately, Photofrin II® has been found to be a complex mixture of monomers, ''dimers'' (dihematoporphyrins formed by ether or ester linkages), and aggregates. Further, the most tumor-localized components are not necessarily the best photosensitizers making pharmacokinetic assessments difficult. Time-resolved fluorescence has been used to differentiate between these various components providing useful information about the uptake, retention, and aggregation dynamics of the drug forms in tumors and tumor-free tissues. In addition, new or unexplored molecules can be characterized as potential lead compounds for PDT based in part on their excited state luminescence lifetimes. Chlorins and bacteriochlorins are currently being investigated by Pandey and others because these agents exhibit high absorbances at higher wavelengths allowing them to be more effectively photoexcited when they are loaded more deeply into cancerous tissue making the treatment of large deep-seated tumors more effective.[33,36]

Our understanding of the complexity of genomes in various cell types has grown considerably with the development of recombinant DNA techniques and sensitive methods for analyzing the organization of specific genes. Such techniques rely on specific nucleic acid hybridization probes which have become irreplaceable in contemporary molecular biology for the detection of specific, complementary nucleic acid sequences. However, stability, detection sensitivity, safety, and disposal problems common to use of radioisotopes (^{32}P, ^{3}H, ^{13}C) have stimulated interest in nonisotopic alternative labels. The high specific activity and simplicity associated with the use of luminescent probes (e.g. acridine), when measured by time-resolved fluorometry, provide powerful nonradioactive substitutes in the field of nucleic acid hybridization. Popular among these alternatives, lanthanide labels covalently bound to nucleic acids have shown unique promise in areas of diagnostic medicine. To date, there have been applications in areas like genetic predisposition to disease including inherited disease, viral infection, bacterial identification, and antibiotic sensitivity testing.[33,34]

A novel technique for screening point mutations was developed for diagnosis of familial defective apolipoprotein B-100 (FDB) by coupling polymerase chain reaction (PCR) performed on the appropriate region of the apoB gene with time-resolved fluorometric detection.[37] Like its cousin familial hypercholesterolemia (FH), FDB affects the interaction between cellular low density lipoprotein receptors and the proper ligands on plasma lipoproteins apoB-100 and apoE. However, unlike FH where a large number of various mutations occur, FDB involves a single point mutation corresponding to amino acid position 3500. In practice, the PCR amplification products are hybridized in situ with Eu^{3+}-labeled oligonucleotides complementary to either the wild type or the mutant genome. This allows the presence or absence of the apoB-100 mutation to be monitored based on the europium chelate excited state lifetimes. When a sample population of 127 Swedish patients clinically diagnosed with heterozygous FH were screened by this method, two were correctly identified as actually suffering from FDB.

By following a similar strategy, a method for simultaneous multicolor analysis of PCR products for any of seven amplified human papilloma virus (HPV) types was reported.[38] HPV infection has been associated with multiple cancer types (primarily anogenital) and identification is, as such, important to determine the risk of cervical carcinoma in women. In this approach, the authors perform a seminested PCR in a single tube using a biotinylated inner primer. Amplification products were captured on streptavidin-functionalized 96-pronged manifold solid supports, and then denatured to render

single-stranded molecules serving as targets in subsequent hybridization reactions. These targets were then probed with a mix of seven type-specific (HPV types 16, 18, 31, 33, 35, 39, and 45 associated with cervical cancer), differentially labeled nucleotides containing 10 or 20 lanthanide chelates at the 5′ ends with seven distinct combinations of Eu^{3+}, Tb^{3+}, and Sm^{3+} ions. After a washing step in microtiter wells, the lanthanide ions were released from the bound probes. This allowed the seven viral strains to be correctly identified by time-resolved fluorescence measurements.

Proteins are dynamic in nature and their function and behavior are intimately related to their structure, conformation, and dynamics. Thus, if one aims to understand and exploit events that rely on protein conformational changes (e.g. protein–drug/ligand association, antigen/hapten–antibody binding, enzyme–substrate interactions, protein–membrane insertion, protein self-association), it becomes necessary to track, quantify, and ultimately understand the behavioral aspects of proteins as they undergo net conformational changes (measurements at or near equilibrium) and particularly as conformations change in near real time. Advances in protein physical chemistry have been made as a result of combining novel fluorescent probes and coupling chemistries with the information rich nanosecond and subnanosecond time-resolved optical techniques. In contrast to techniques like NMR and X-ray crystallography, subnanomolar protein concentrations can routinely be studied by fluorescence allowing assessment of association parameters under true equilibrium conditions. Recent results by Ingersoll et al.[39] illustrate the potential of on-the-fly phase-modulation fluorescence to track the nanosecond and subnanosecond dynamics of BSA-Ac. In these experiments, the authors determined the temporal evolution of fluorescence anisotropy and intensity decay kinetics of BSA-Ac when it was challenged with trypsin or β-mercaptoethanol (BME) (Figure 7). Both the BME-induced disulfide interchange and the trypsin-mediated protein digestion were successfully tracked on-the-fly by multiharmonic Fourier fluorescence suggesting the potential of dynamic optical techniques for real time reaction monitoring.

Molecular behavior at interfaces is of critical importance in areas ranging from energy conversion, chromatography, and catalysis to toxicity, adhesion and transport properties, and chemical sensing. By using time-resolved fluorescence in concert with interfacially selective detection (generally by exploiting some total internal reflection configuration), the underlying kinetics and mechanisms associated with surface bound molecules can be accessed even in aqueous media.[40] Such information is relevant to the study of biosensor interfacial dynamics where the ultimate performance is governed by

Figure 7 On-the-fly frequency domain MHF intensity decay data for BSA-Ac reacting with BME. (a) Multifrequency phase angle (●, ○) and demodulation factor (■,) data before and after reacting for 90 min with BME. Filled points, 0 min, open points, 90 min. (b) Residuals, frequency-dependent phase ( ) and modulation (Δ) plots for frequency domain data sets acquired on-the-fly at the times indicated. The fractional intensities associated with τ_1 and τ_2 are shown. The apparent excited state fluorescence lifetimes associated with f_1( ) and f_2 (▽) are 3.97 ± 0.08 ns and 1.21 ± 0.04 ns, respectively and they are independent of reaction time. (Reproduced with permission from Ingersoll et al., *Applied Spectroscopy*.)[39]

the complex interplay among the biorecognition element (BRE) structure and the conformation at the interface, the ease with which the target analyte can reach and interact with the BRE, and the homogeneity, stability, and mobility of the BRE at the interface. In this context, the Bright group developed multifrequency phase modulation total internal reflection fluorescence (MPM/TIRF) to study in situ the interfacial distribution of surface immobilized BRE dynamics.[41] Initial work showed that an immunosurface composed of F(ab′) antifluorescein polyclonal antibodies at a fused silica surface on interacting with free fluorescein hapten consisted of a broad distribution of microdomains. In contrast, the F(ab′)–fluorescein system in solution was described by a single discrete microdomain (i.e. excited state fluorescence lifetime).

That is, an ensemble of F(ab′) fragments having slightly different binding site accessibilites, surface-induced conformational changes, and/or actual affinity constants exists at and is modulated by the surface. Also, these species change/drift with storage time causing loss of immunosurface integrity over time.

A powerful hybrid technique called phase-resolved evanescent wave induced fluorescence (PREWIF) was reported by Lundgren et al.[42] for studying interfaces by combining the interfacial selectivity inherent to TIRF (total internal reflection fluorescence) with the temporal and spectral resolution of phase-resolved fluorescence. The potential of PREWIF for in situ studies of heterogenous interfaces under ambient conditions was demonstrated by resolving individual components within thin sol–gel-derived glass films doped with TNS/PRODAN (toluidinyl naphthalene sulfonic acid/6-propionyl-2-(*N*,*N*-dimethylamino)naphthalene), rhodamine 6G (R6G)/eosin Y, or R6G monomer/R6G. These researchers were also able to resolve the static emission from an ~100 Å thick immunosurface composed of protein G-antifluorescein-bound fluorescein even in the presence of excess free fluorescein in the bulk. PREWIF was also used to recover the relaxed and unrelaxed spectra contributing to the overall fluorescence from BSA-Ac physisorbed onto a quartz surface.

5 POLYMER PHOTOPHYSICS

Processes involved in polymer chain dynamics span a wide range of time and lengthscales. The large scale motions of polymer chains have historically been analyzed in terms of normal modes where higher order modes correspond to motions on faster timescales and on shorter lengthscales. Polymer chain dynamics on sufficiently short lengthscales depend greatly on the chemical structure of the polymer chain itself.[43–50] Polymer photophysics, both in its historical development as well as its current practice, can be divided into a few regimes of study: excimer formation, fluorescence anisotropy, fluorescence quenching, and excited state energy migration. Time-resolved optical spectroscopy provides a uniquely detailed picture of local segmental motion during polymer chain dynamics.[43] This is accomplished by observing the time dependence of the polymer orientation autocorrelation function directly. A common feature of time-resolved fluorescence methods is the use of nonfluorescent polymer chains with an extrinsic chromophore label attached. Alternatively, the emission from an intrinsic polymer-bound fluorophore can be used to investigate the energy migration as well as polymer.[43,44]

A typical time-resolved fluorescence experiment measures the rotational reorientation of a fluorophore. If the said fluorophore is part of a polymer chain or in registry with the chain, then polymer chain motions can be inferred by observing the chromophore rotational reorientation. The detection limits of fluorescence allow such measurements to be made even at a level of one chromophore per 1000 oligomeric repeat units (i.e. a chain concentration of 0.1%). When a chromophore with a strongly polarized electronic transition is excited by polarized light, those chromophores with absorbance transition moments aligned in the direction of the excitation polarization are preferentially excited. If these chromophores emit before they significantly reorient or depolarize, the fluorescence will also be preferentially polarized (i.e. anisotropic) along this direction. The fluorescence polarization depends upon the interrelation of two physical parameters: the excited state fluorescence lifetime and the molecular rotational reorientation time.[44]

Most of the work using time-resolved fluorescence to investigate local polymer dynamics has been performed using dilute solutions of fluorescently labeled polymers.[44] These studies provide an opportunity to understand local chain motions without considering the complicating effects of chain–chain interactions present in more concentrated systems. It is important to mention here that the timescales for local dynamics in solution are comparable to the fluorescence timescale. Recently, a charge transfer fluorescence molecule was used as a probe to study the structure of polystyrene latices and polystyrene–glycidylmethacrylate core–shell latices.[45] Information on the composition of the latex was obtained by using steady-state and time-resolved fluorescence measurements. The fluorescent probe, PCNMP, that was used in these studies has a dipolar excited state which is populated by excitation in the ultraviolet range by an intramolecular electron transfer process. As is typical for charge transfer luminescence, however, the emission spectra are rather broad, limiting static fluorescence to qualitative observations because the broad emission spectra make it difficult to distinguish between several coinciding species. By using excited state intensity decay information as an additional experimental observable, Hofstraat et al.[45] were able to provide a clearer picture of such a complicated system.

In another study, time-resolved fluorescence spectra of poly(*N*-vinylcarbazole) in solution were analyzed by using a principal multivariate spectral estimation method.[46] The data clearly indicated that the polymer emission spectra were composed of precisely three emitting species (monomer, partial overlap excimer, and sandwich excimer). Intensity rise as well as decay curves of the fluorescence of each component are complex and depend on the polymer tacticity. These authors determined that the partial overlap excimer was formed not only by ultrafast trapping in the pre-existing site

but also through dynamic processes such as energy migration. It was further reported that the excited state monomer and the partial overlap excimer were produced via sandwich excimer dissociation and reactivation. In organized molecular systems, structural inhomogeneity, giving rise to various excited state species is ubiquitous, suggests the broad applicability of such an approach.

Time-resolved fluorescence anisotropy measurements are particularly attractive because they allow work to take place under dilute conditions and they provide an intrinsic molecular ruler (i.e. the dimensions of the fluorophore). Time-resolved fluorescence anisotropy techniques have been used to investigate fluorophore–polymer interactions in the bulk, to follow subunit dynamics, and to track the motion of the elastic cross-link junctions within various polymers. According to Soutar et al., in studies of macromolecular dynamics, emission anisotropy measurements are the most informative of the luminescence-based approaches that can be adopted.[47,48] Fluorophores simply dispersed in the medium of interest can furnish information on the local free volume accessible to the probe whereas covalently bound fluorophores can reveal details regarding the kinetic behavior of chain segments, termini, and substituent groups. Bolstering their claims, Soutar et al. reported on the intramolecular segmental relaxation behavior of poly(methyl methacrylate) (PMMA) and poly(methyl acrylate) (PMA) at low concentration dissolved in dichloromethane by using time-resolved fluorescence anisotropy.[47] The fluorescence anisotropy decay kinetics of each polymer, over the temperature range of 230–310 K, were adequately described by single exponential models for acenaphthylene- and 1-vinylnaphthalene-based labels. The recovered rotational reorientation times for segmental motion exhibited an Arrhenius dependence in the temperature range studied, giving rise to activation energies of 14 and 11 kJ mol^{-1} for PMMA and PMA, respectively. These values are considerably lower than those reported for either polymer in other common solvents. In fact, the magnitude of the differences in activation energies are too large to be explained on the assumption that the solvents function solely to provide frictional resistance to the polymer dynamics. These authors suggested that: (1) PMMA and PMA exhibit specific interactions with dichloromethane and/or other solvents, such as toluene or (2) the naphthyl labels may actually experience specific interactions with dichloromethane which distort the apparent polymer behavior.

Stein, Hoffman, Frank, and Fayer have used time-resolved fluorescence anisotropy decays to investigate the reorientational dynamics of a cross-link junction in poly(dimethylsiloxane) networks from a chromophore attached to the cross-link between $T_g + 75$ K to $T_g + 150$ K.[49] At the junction, the probe chromophore, 1-dimethylamino-5-sulfonylnaphthalene amide (dansyl amide), lies pendant to a silicon that acts as a trifunctional cross-linking atom. In cyclohexanol, the fluorescence anisotropy decays for the chromophore are in agreement with the Debye–Stokes–Einstein hydrodynamic theory of rotational diffusion, demonstrating that the cross-linker can be used as a probe of reorientational relaxation. The fluorescence anisotropy decay kinetics are remarkably fast for a cross-linked poly(dimethylsiloxane) network, reflecting fast rotational reorientation of the cross-link junction. This reorientation appears diffusive and has a temperature dependence in accord with the Williams–Landel–Ferry equation.[49] A model was proposed suggesting that reorientational and translational motion of the cross-link occur simultaneously and both are coupled to fluctuations of the polymer chain termini.

Niemeyer and Bright used time-resolved fluorescence anisotropy and reported on the effects of polymer molecular weight, temperature, and near- and supercritical CO_2 gas sorption on the rotational reorientation dynamics of a model solute, *N*,*N*′-bis-(2,5-di-tert-butylphenyl)-3,4,9,10-perylenedicarboximide (BTBP), dissolved in poly(dimethylsiloxane).[50] These authors showed that there is a linear correlation between the BTBP rotational reorientation time and the poly(dimethylsiloxane) polymer bulk density. Temperature-dependent studies of the BTBP/poly(dimethylsiloxane) system showed that the BTBP rotational reorientation dynamics are accurately described by an Arrhenius activation model where the recovered activation energies for the BTBP rotational reorientation are statistically equivalent to those for poly(dimethylsiloxane) viscous flow. The addition of CO_2 to the BTBP/poly(dimethylsiloxane) system led to appreciably decreased BTBP rotational reorientation times with increased CO_2 pressure. These results illustrate how polymer dilation by CO_2 can be used to tailor the dynamics within polymer systems.

6 APPLICATIONS IN THE SEPARATION SCIENCES

Because the chromatographic retention time and excited state fluorescence lifetime of a solute are independent phenomena, they contain orthogonal information about the identity of a particular analyte. Time-resolved fluorescence techniques have been applied to reverse-phase HPLC (high-performance liquid chromatography), capillary electrophoresis (CE) and other separation techniques.[51–56]

Loss in selectivity due to overlapping peaks is a major problem encountered in the detection process based on retention times alone. Further, detection at only one or a

few emission/excitation wavelengths may be inadequate to resolve overlapping ''chromatographic'' peaks, while the use of an array detector to collect an entire spectrum can decrease sensitivity as a result of dispersion. Thus, if selectivity is not substantial, it may be impossible to detect the presence of minor components or matrix effects.[53] Lytle et al. pioneered using time-resolved fluorescence to identify and resolve overlapping chromatographic peaks as well as to indicate the presence of impurities and matrix effects.[51] In the Lytle method, the eluent excited state fluorescence lifetime is determined on-the-fly during liquid chromatographic separation. The lifetimes provided the additional selectivity needed to confirm peak assignments based on retention time. Lytle and his associates emphasized that a combination of coarse excited state fluorescence lifetime measurement and retention time yielded more information about the identity of an unknown than extremely refined measurement of either one alone. The Lytle measurements were made in the time domain by using a pulsed laser for excitation and a PMT detector. The PMT anode current was split in half and one portion was delayed by 10 ns before being sent to one input of a two-channel oscilloscope. Two intensity chromatograms were thus obtained representing two different delay times separated by 10 ns. A ratio of the two chromatograms provided a ratiogram in which each lifetime was identified by a unique concentration-independent ratio, whereby a changing ratio across a peak was indicative of coelution. Results of experiments with polycyclic aromatic hydrocarbon (PAH) standards of known identity were used to illustrate the methodology. Further, 15 PAHs were positively identified in combustion products, illustrating the applicability of these lifetime chromatography measurements to real samples.

Frequency domain fluorescence has been used to detect and resolve overlapping peaks on-the-fly in reverse-phase HPLC.[52–54] Direct, simultaneous measurements of fluorescence intensity, phase-shift, and demodulation were made at 1 s time intervals for PAHs as they eluted from the chromatograph.[52] During early investigations, these experiments were hindered by limitations of the frequency domain spectrofluorometers, which could only collect data at one modulation frequency per chromatogram thereby necessitating multiple sample injections. The resulting chromatograms had to be perfectly overlaid and the data combined at each point along the chromatographic peaks.[52] Smalley et al.[53,54] have investigated on-the-fly fluorescence lifetime detection in HPLC using a MHF phase-modulation spectrofluorometer,[19,20] which eliminates the problem of multiple injection and offers other advantages as well. These authors showed that the MHF data acquired on-the-fly during a single chromatographic run contained all the information needed to determine the eluent excited state fluorescence intensity decay kinetics and to indicate and resolve overlapping peaks at intervals as short as several milliseconds. This allowed essentially continuous monitoring of the intensity decay kinetics and static emission intensity during chromatographic elution. This work demonstrated accurate lifetime detection and peak resolution for simple mixtures of PAHs by HPLC. This technique can be used for component identification, indication of coeluting peaks, matrix effects or impurities, and resolution of overlapping peaks. This technique also requires no a priori assumptions about spectral features, chromatographic peak shapes, or fluorescence lifetimes.

Soper et al. investigated the dynamic (on-line) measurement of excited state fluorescence lifetimes for several chromophores separated by free solution CE using time-correlated single-photon counting with NIR (near-infrared) excitation.[55] The chromophores used in this work were tricarbocyanine dyes that show absorption and emission properties in the NIR and possess excited state lifetimes between 500–1000 ps. The instrument used for this study consisted of a solid-state, passively mode-locked Ti-sapphire laser for excitation and a single photon avalanche diode detector operated in a Geiger mode (Figure 8). The instrument response function of this device was 165 ps fwhm, appropriate for making subnanosecond lifetime measurements in CE applications. The authors demonstrated electrophoretic separation of two NIR dyes, DTTCl (cationic) and IR-125 (anionic), in a 95 : 5 methanol : water running buffer (pH = 9.5). The excited state fluorescence lifetimes were calculated using maximum likelihood estimators (MLE) methods.[55] At a loading level of 1.42 zmol for IR-125 and 49 zmol for DTTCl, the excited state fluorescence lifetime values were determined to be 482 ± 14 ps for IR-125 and 943 ± 23 ps for DTTCl, which agreed favorably with the values determined for these dyes at high concentrations in static solutions. To demonstrate the feasibility of making excited state fluorescence lifetime determinations in capillary gel electrophoresis, where the gel can produce high scattering backgrounds, the excited state fluorescence lifetimes of C-terminated fragments (produced from the M13 mp 18 template labeled at the 5′ end of a universal M13 sequencing primer with a NIR fluorescent tag) were determined. The mean excited state fluorescence lifetime for 30 different peaks in the electropherogram was 581 ps and the standard deviation was 9 ps.

On-the-fly frequency domain fluorescence lifetime detection in CE was demonstrated by Li and McGown.[56] Virtually continuous detection was achieved by interfacing a commercial CE instrument with a commercial MHF instrument. These authors modified the CE capillary cartridge to allow the capillary to pass through

Figure 8 NIR time-correlated single-photon counting instrument used for excited state fluorescence lifetime determinations in a CE experiment. (Adapted from Smalley et al.)[53]

a specially constructed capillary column mount capable of being micropositioned within the MHF sample chamber. Fluorescence intensity and intensity decay data were recovered from the dynamic MHF data. These data were analyzed using conventional nonlinear least squares or the MEM. The latter method allowed these authors to recover the intensity decay kinetics without a priori knowledge of the system decay function.

7 CHARACTERIZATION OF ORGANIZED MEDIA

Microheterogeniety has been observed in a variety of chemically and biologically organized systems, such as normal and reverse micelles, lipid vesicles, ion-exchange membranes, and cyclodextrins. Applications of time-resolved fluorescence spectroscopy toward the investigation of such systems are widespread.[57–70]

Huang and Bright examined the microenvironments within sodium dodecyl sulfate (SDS) micelles by using two fluorescent probes, 2-anilinonaphthalene-6-sulfonic acid (2,6-ANS) and *N*-phenylnaphthylamine (1-AN).[58] The excited state intensity decay kinetics were recovered by multifrequency phase and modulation measurements and analyzed using a global analysis protocol. The results showed that the fluorescence intensity decay kinetics of 2,6-ANS, which probes the outer core region (i.e. the palisade layer) of SDS micelles, was characterized by a unimodal Lorentzian lifetime distribution. In contrast, a single discrete excited state fluorescence lifetime was observed for 1-AN, which positioned itself in the micelle inner core region. The intensity decay kinetics of these probes were investigated as functions of temperature, counter-ion (Na^+ and Mg^{+2}) concentration, and linear alcohol cosolvents (*n*-butanol, *n*-pentanol, *n*-hexanol, and *n*-heptanol). Their collective results confirmed that the outer-core region of SDS micelles is microheterogeneous while the inner-core is essentially homogeneous. In addition, the intensity decay kinetics and the outer-core probe, 2,6-ANS, partitioning appeared to be more sensitive to variations in temperature and counter-ions in comparison to those of the inner core probe, 1-AN. The authors proposed that this observation was a result of different degrees of water penetration in the outer-core region. In the SDS system, the effects of micelle polydispersity and compositional diversity on the environmental microheterogeniety of the fluorescent probe seem to be minimal in comparison to water gradient effects.

Water immobilization at surfactant interfaces in reverse micelles has been investigated extensively.[59–64] For example, several research groups have examined the dynamical response of water in aerosol OT (AOT) reverse micellar systems.[59–64] Zhang and Bright investigated the reorganization of water within AOT reverse micelles on the nanosecond timescale using fluorescence spectroscopy of 1,8-anilino-8-naphthalenesulfonic acid (ANS).[60] For water loading $w_0 < 2.5$ ($w_0 =$ [water]/[AOT]), they observed two relaxation processes with time constants of 0.5–1.7 ns and 3.5–11.8 ns that they attributed to ''free'' and ''bound'' water reorganization,

respectively. For $w_0 > 2.5$, however, a single reorganization process with a time constant of 0.8–1.2 ns was reported. In general, they found that the observed rate constants decreased with increasing w_0. Cho et al.[61] have also probed the AOT interior using ~50 ps time-resolved fluorescence of ANS and suggested that the water molecules near the surfactant interface were ice-like owing to the strong interactions with the polar headgroup surface of high curvature and that the molecules appear bulk-like ~6–18 Å from the interface. Sarkar et al.[62,63] performed time-resolved fluorescence measurements of the probe coumarin 480 in micellar solutions and observed fluorescence decays with time constants ranging from 1.7–12 ns. They also attributed these dynamical changes to relaxation processes of water molecules in various water pool environments. Mittleman et al.[64] used ultrafast spectroscopy to probe the dielectric relaxation of water in AOT reverse micelles. These authors found that the timescale and relaxation amplitude are smaller than those of bulk water. This result was explained in terms of reduced long-range collective behavior resulting from the small water pool in the reverse micelles. Levinger et al. investigated the mobility of water in water/AOT/isooctane reverse micelles by using polar solvation dynamics measurements using ultrafast, time-resolved fluorescence up-conversion spectroscopy.[59] The major results of their work revealed that interactions of water with the surfactant headgroups in AOT reverse micelles effectively eliminates bulk-like solvent dynamics. This was most evident for very small reverse micelles, $w_0 < 5$. As the water pool volume increased in the AOT reverse micelles, more and more water molecules became free to move. This was manifested in a dynamic relaxation event on a timescale comparable to that of bulk water. However, although the solvation dynamics in the largest reverse micelles revealed a considerable fast relaxation component, the overall dynamics were still slower than that observed for bulk water. This suggests that solvent motion within a reverse micellar environment is affected by the surfactant interface.

Characterization of short-lived intermediates in microheterogeneous systems has been carried out by Whitten et al. using time-resolved spectroscopic techniques.[65] The intensity decay kinetics for a series of *trans*-stilbene-derivatized amphiphiles, which readily form bilayer systems in aqueous media, were analyzed by using a lifetime distribution analysis. The results indicated that the observed fluorescence originates from different types of excited state species that consist of two or more *trans*-stilbene units; one emission feature was attributed to the excited state of a ground state aggregate while the other was assigned to an excimer that may arise from a ''defect'' in the bilayer. The complex exponential nature of the decay kinetics was attributed to distributions of environments experienced by the fluorescing species.

Dimer formation of naphthalene in Langmuir–Blodgett (LB) monolayer films was probed by time-resolved fluorescence spectroscopy by Yamazaki et al.[66] Naphthalene incorporated in LB monolayer films exhibited two types of fluorescence emission due to monomer and dimer species. The dimer fluorescence corresponded well to that observed in the naphthalene crystal under extraordinarily high pressure and in naphthalene paracyclophanes. These researchers also reported on the excitation energy relaxation in LB films with rhodamine B, oxacyanine, and pyrene by means of picosecond time-resolved fluorescence spectroscopy. They found that the LB film is characterized by: (1) an inhomogeneous distribution of guest chromophores with fractal or fractal-like structures, (2) the formation of dimers and/or aggregates of dyes in molecular cages compressed within the fatty acid matrix, and (3) excimer formation from the preformed dimers. Their experimental results indicated that naphthalene chromophores were distributed within the LB monolayer films randomly as expected from statistical calculations. Further, naphthalene in LB films of low and medium concentrations (<10 mol%) was dispersed uniformly and randomly as monomer much more than for pyrene or ionic dyes like oxacyanine and rhodamine B, in which cases even low concentrations (1 mol%) resulted in dimer and/or excimer formation.

Cyclodextrins have drawn significant attention over the last few decades primarily because of their simplicity and the utility of these systems as models for protein–ligand and enzyme–substrate binding. In earlier work, Bright et al. presented nanosecond and picosecond time-resolved fluorometric studies of fluorophore-β-cyclodextrin inclusion complexes.[67] They found that the recovered intensity decay results for various anilinonaphthalenesulfonate ANS probes (2,6-ANS, 2,7-ANS, 2,8-ANS, and 1,8-ANS) with β-cyclodextrin are not well described by single or double exponential decay models. Their experimental data demonstrated that the fluorescence intensity decay kinetics of ANS-β-cyclodextrin inclusion complexes are modeled most accurately by Gaussian or Lorentzian lifetime distributions. In turn, this indicates that there is an ensemble of similarly formed ANS-β-cyclodextrin complexes in coexistence. This, the authors proposed, arose from rapid exchange between free and cyclodextrin-bound ANS complexes.

Wirth and Burbage used frequency domain fluorescence anisotropy decays to characterize the adsorbate reorientation and dynamics at a water/(octadecylsilyl)silica interface.[68] These authors showed that one can

independently study the fluorophore rotational reorientation in the surface plane can be studied independently as well as rotations out of the surface plane. Acridine orange, the fluorescent probe used in this work, exhibited hindered rotational reorientation for its out-of-plane rotation and it rotated slowly in the surface plane. The authors suggested that acridine orange resides at the interface of water and octadecylsilane and it senses the local morphological changes at this interface.

Montgomery and Wirth also investigated the effects of SDS surfactant concentration, above and below the SDS critical micelle concentration (CMC), on the rotational reorientation dynamics of a hydrophobic probe, 1,4-bis[*o*-methylstyryl]benzene, in a monolayer of covalently bonded dimethyloctadecylsiloxane chains.[69] The results showed that for any level of added SDS, the probe reorientation was less hindered than that measured for a pure water mobile phase. The net effect of SDS was to make the hydrophobic environment on the surface more fluid. However, near the SDS CMC, unusual behavior was observed and the probe rotational motion was even less hindered than it was above or below the CMC.

The adsorption of premicellar SDS onto methylated (C_1) silica surfaces was also studied to explore the possibility of monomer physisorption at an interface.[70] Methylation provided a hydrophobic surface precluding SDS chain interpenetration into the methyl monolayer. The premicellar adsorption maxima were found to be smaller for the C_1 surface than for the *n*-octadecylsiloxane (C_{18}) surface. This implicates interpenetration as an important factor in premicellar adsorption maxima. Surface roughness was also found to increase the premicellar adsorption maximum on the C_1 surface. The rotational reorientation behavior of acridine orange on these surfaces points to a structural transition in the adsorbed SDS layer as the origin of the large premicellar adsorption maximum of SDS on C_{18}.

8 FLUORESCENCE LIFETIME IMAGING MICROSCOPY

Fluorescence microscopy is an indispensable tool in the biosciences because of the excellent detection limits and the environmental responsiveness of selected probes and stains. However, steady-state microfluorimetry is inherently limited because it is more difficult to deconvolve the contributions from multiple ''emissive'' species, including autoluminescence from intrinsic cellular components, Raman scatter, and quantification problems exacerbated by difficulties in measuring quantum yield profiles across a substrate. In contrast, fluorescence lifetime imaging microscopy (FLIM) does not suffer from the inherent drawbacks of steady-state techniques and provides a means of acquiring information on the organization, structure, and dynamics of complex tissues, cells, and subcellular structures.[71]

In FLIM, the spatial (two- or three-dimensional) distribution of fluorescence decay times are determined directly at every pixel of an image simultaneously. The high temporal and spatial resolution is extremely important because it allows dynamic environmental parameters to be monitored in a spatially defined manner in the specimen under study (e.g. a single living cell). The intrinsic molecular information provided by dynamic measurements also minimizes background concerns and, as the excited state fluorescence lifetime is the only physical attribute observable, the resulting image is, in effect, simplified and filtered to include only the most analytically useful information. Judicious use of fluorescent reporter groups which exhibit excited state lifetime changes when challenged by specific intracellular factors allows one to quantitate such things as environmental membrane potential, temperature, dipolarity, and metabolic chemistries (H^+, K^+, Ca^{2+}, Zn^{2+}, O_2, glucose). The fluorophore/macromolecule mobility can also be assessed and information obtained at the nanometer level using resonance energy transfer techniques.

Since it was first demonstrated in 1990 by Wang et al.[72] that spatial variations in fluorescence lifetimes could be used as a source of image contrast, FLIM has received considerable attention as a powerful noninvasive method for obtaining spatially resolved information at the subcellular and even the molecular level. With state-of-the-art instrumentation, the total data acquisition time required to obtain a FLIM image with the diffraction-limited spatial resolution is typically ~30 s allowing the acquisition, processing, and display of fluorescence lifetime-resolved images in quasi-real time. Although this timescale is rapid enough for many applications, efforts are currently underway to complete this task in less time. Rapid, real time data acquisition would create new possibilities in areas including lifetime imaging endoscopy, large scale medical prescreening and diagnosis, pharmaceutical and medical microplate assays, combinatorial library evaluation, tracking biochemical kinetics, and tracing metabolic pathways.

Great advances in the ability to study dynamic events by FLIM were made by Schneider and Clegg.[73] These authors reported a new instrument capable of acquiring and displaying a time-resolved image in under 200 ms. Gratton et al. have also reported on a scanning fluorescence microscope using an asynchronous pump–probe approach which provides improved spatial

resolution compared to conventional one-photon fluorescence microscopy.[74] Lakowicz et al.[75] demonstrated the suitability of phase supression techniques to FLIM for minimizing the contribution from a particular decay time (i.e. species). For example, in the phase-resolved difference image, acrylamide-quenched Y_t-base emission was nulled leaving only a residual signal from Y_t-base present in inaccessible (unquenchable) environments. Lakowicz et al. were also the first to produce a fluorescence lifetime-based cellular chemical profile by tracking intracellular Ca^{2+} concentration in COS cell lines using the probe Quin-2.[76]

Although in its infancy, advances such as these in concert with rapid improvements in laser sources, electro-optic modulators, intensified CCD (charge coupled device) array detectors, computer processing algorithms, and bioreagents (monoclonal antibodies, nucleic acid probes, fluorescent labels) are sure to make FLIM a more accessible, popular, and routine technique in the analyst's arsenal.

9 FLUORESCENCE LIFETIME-BASED SENSING

Fluorescence-based sensing can rely on intensity, intensity ratio, or excited state intensity decay kinetics measurements. Although simple in concept and instrumentation, fluorescence intensity based sensing can be confounded by several factors. Frequent recalibration and other corrections are thus required because the fluorescence intensity depends on excitation intensity, light losses in optical fibers, photobleaching, and changes in the light scattering and/or sample absorption characteristics.[77–84] Wavelength-ratiometric fluorescent probes avoid some of these problems, however, lack of known and systematic methods to create such probes as well as limited commercial availability has hindered the widespread use of this approach. Because excited state fluorescence lifetime measurements are insensitive to probe concentration, photobleaching, washout and excitation instabilities, lifetime-based methods offer new opportunities for chemical sensing. Additionally, application of fluorescence lifetime-based sensing to remote monitoring with fiber optics renders recalibrations and corrections needed with intensity measurements unnecessary.[77–85]

Fluorescence lifetime-based sensing can be based on various molecular level physical or chemical processes and approaches such as collisional quenching, energy transfer, lifetime-based sensing using intrinsic versus conjugated probes, and so on.[78] For example, Draxler and Lippitsch have developed an optical pH sensor based on different fluorescence decay times of acid and base forms of the indicator diethylaminomethylpyrene.[79] The fact that the amino group is decoupled from the chromophoric system, excited state electron transfer probability from the amino group to pyrene influences the fluorescence decay times. This pyrene-based indicator was sequestered within a polyurethane-based hydrogel matrix providing the aqueous environment necessary for the acid–base reactions. The sensor has a favorable pK_a value (viable over the entire physiological pH range), an acceptable response time, and low cross-sensitivity against other cations. According to the researchers, reproducibility and long-term stability are the exceptional properties of this sensor.

Szmacinski and Lakowicz measured the pH-dependent fluorescence decay times of the seminaphthofluoresceins (SNAFL) and seminaphthorhodafluors (SNARF) using frequency domain fluorometry and an inexpensive 543 nm He–Ne laser light source.[80] They found that phase and modulation values were strongly dependent on pH in the physiological pH range as well as on the excitation and emission wavelengths. This dependence allows the range of pH sensitivity to be chosen by selection of wavelength(s) and enables increased precision of pH measurements by use of phase and/or modulation measurements at several wavelengths.

Recently, Chang et al.[81] developed a fluorescence lifetime-based sensor for water, by immobilizing a solvent-polarity-sensitive fluorescent metal–ligand compound, dipyridol[3,2-*a*:2′,3′-*c*]phenazine, di[*cis*-1,2-bis(diphenylphosphino)ethylene]osmium(II) hexafluorophosphate by ionic bonding onto a carboxymethyl cellulose cation-exchange resin, sandwiched between a thin sol–gel-processed layer and a glass substrate. When this solid film sensor is inserted from a water-free into a water-containing organic solvent, a decrease in fluorescence lifetime was observed due to fluorescence quenching. Because of the long decay time of this compound the frequency domain measurements could be performed using an inexpensive amplitude-modulated commercial blue LED. For example, the sensor exhibited a 39.6° phase angle decrease at a 2 MHz modulation frequency when placed from anhydrous acetone into a mixture of 20% (v/v) water in acetone. Similar observations were noticed in five other organic solvents upon addition of water. For this sensor, the response and recovery were both complete within seconds and the detection limit was solvent dependent. With ethyl acetate, the detection limit was as low as 0.02% (v/v) of water. This sensor also displayed excellent long-term stability with little drift in performance after a period of two months. Based on similar principles and instrumentation, these researchers designed a fluorescence lifetime-based sensor for methanol.[82]

The solvatochromic dye used in this case was tris(4,4′-dicarboxy-2,2′-bipyridine)ruthenium(II) hexafluorophosphate which was dissolved in a PMMA solution to form a thin film in a similar manner as in the case of the water sensor.

Birch et al. have demonstrated an optical method for the selective detection of Cu(II) ions in water using time-resolved fluorescence resonance energy transfer from the xanthene dye rhodamine 800 encapsulated in a Nafion-based sensor platform.[83] They showed that fluorescence quenching of the probe rhodamine 800 by other potentially interfering metal ions such as cobalt, nickel, and chromium were negligible in comparison to copper. They used a 670 nm picosecond diode laser as the excitation source and time-resolved single-photon counting for detection. They were able to determine Cu(II) between 5 and 50 mM. They estimated that the lower limit of detection for the sensor was 10 ppb.

Fluorescence lifetime-based biosensing of zinc was demonstrated by Thompson and Patchan by using frequency domain fluorescence and 5,1-dansylamide as the probe.[84] Briefly, the fluorescence lifetime of the bound dansylamide inhibitor increased approximately sevenfold and the emission was blue shifted 100 nm relative to the corresponding values for the free probe. The carbonic anhydrase/dansylamide indicator system permitted measurement of zinc concentration range over more than three decades.

Draxler and Lippitsch investigated the influence of the microenvironment on the fluorescence behavior of indicator molecules during lifetime-based sensing.[85] The two examples discussed were for a pH sensor using a pyrene-based fluorophore sequestered within a hydrogel and a ruthenium complex for oxygen sensing embedded in a polystyrene membrane. The interactions of a luminophore with a polymer matrix influence its luminescence decay properties. In many cases, deviations from a single-exponential decay could be observed, which may be due to spatial nonuniformity in the matrix refractive index, variations in the chromophore steric stabilization by the polymer environment, or nonresonant energy transfer from the luminophore to acceptor sites within the matrix. These authors also showed that this nonresonant energy transfer leads, at least in the case of a homogeneous distance distribution between luminophores and quenching sites, to a simple mathematical description of the luminescence decay which needs only one additional parameter. They proved the suitability of this approach in experimental assessment with these two different luminophores each in a different polymer. For the examples given, the proposed model gave a physically reasonable and more tractable procedure for evaluating luminescence decay kinetics when compared to multiple-exponential or rate-distribution models.

10 MULTIPHOTON EXCITED FLUORESCENCE

The high peak powers available from picosecond and femtosecond lasers can result in multiphoton excitation, wherein the fluorophore simultaneously absorbs two or more long wavelength photons to yield an excited singlet state. Multiphoton excitation requires high peak powers to increase the probability that two or more photons are simultaneously available within a given molecular volume for excitation. Because of the interactions of two or more photons with the fluorophore, the selection rules governing these transitions are different from those for one-photon excited fluorescence.[86] The interest in multiphoton excitation has increased dramatically as the result of its applications to time-resolved fluorescence and fluorescence microscopy. Several research groups have demonstrated time-resolved multiphoton excited fluorescence in the time and frequency domains as a tool for determining excited state anisotropy and intensity decay kinetics.[21,86–92] Two-photon induced time-resolved fluorescence has been observed for a wide variety of biochemical fluorophores, including membranes labeled with 1,6-diphenyl-3,4,5-hexatriene, labeled DNA, and proteins.[86,87] Lakowicz et al. have reported extensive investigation regarding multiphoton excited luminescence from biochemical fluorophores using the frequency domain technique.[86,87] The primary advantages associated with the frequency domain methodology are its high accuracy and the speed with which the phase angle and demodulation factor can be measured.[86,87]

Bright et al. reported on the performance of a new multiharmonic frequency domain instrument that uses the high harmonic content of a passively mode-locked pulse-picked femtosecond Ti-sapphire laser as the excitation source for the determination of one-, two-, or three-photon excited time-resolved fluorescence anisotropy and intensity decay kinetics.[21] The new instrument uses a parallel data acquisition strategy[19,20] which allows complete frequency domain data sets to be acquired in as little as 30 s. They demonstrated the potential of this new instrument by measuring the excited state fluorescence lifetimes and rotational reorientation times for fluorophores and fluorophore mixtures that exhibit nanosecond and subnanosecond single exponential and mutiexponential decay kinetics under one-, two-, or three-photon excitation. The instrument was able to recover the fluorescence decay kinetics accurately and offered a measurement precision on the order of 5–10 ps. The

instrument's capabilities were further tested by performing time-resolved intensity decay measurements on dilute fluorophore solutions in optically dense samples such as bromocresol green (shown in Figure 9) and undiluted whole blood under two-photon excitation conditions. The results of these experiments showed that the new instrument can recover the true fluorophore decay kinetics accurately in these optically dense samples. They also demonstrated the speed of the new instrument by recording the time-resolved anisotropy decay kinetics associated with fluorescein-labeled bovine serum albumin (BSA-FL) under two-photon excitation conditions on-the-fly as it was digested by the enzyme trypsin (Figure 10). Complete, 100 frequency data sets were acquired on-the-fly every 30 s. The results provided insights into the complex events that occur as BSA-FL is digested by trypsin. The time resolution of the new instrument is currently limited by the PMT detectors which set the practical upper modulation frequency limit to between 250–300 MHz.

Birch et al. have recently developed a time-correlated single-photon timing nonlinear fluorometer for recording the fluorescence decay times and rotational reorientation times of molecular probes using 120 fs regeneratively amplified Ti-sapphire laser excitation via simultaneous nonresonant absorption of two or more NIR photons.[88] A microchannel plate photomultiplier giving 70 ps impulse response is used for detection. Studies on 1,6-diphenylhexatriene, R6G, and *p*-terphenyl in propylene glycol demonstrated two- and three-photon induced fluorescence characteristics. Time-resolved detection of

multiphoton induced anisotropic fluorescence using TCSPC techniques confirm that a higher degree of molecular orientation for two- and three-photon excitation is obtained in comparison to one-photon excitation. Multiphoton excitation, therefore, suggests itself as a more sensitive means of acquiring fluorescence anisotropy decays when probing the dynamics and structure of nanoscale microheterogeneous systems such as biomembranes, porous sol–gel glasses, and molecular matrices by observing molecular rotation of the fluorophore. Moreover, time-resolved multiphoton induced fluorescence studies using TCSPC offer potential in other applications, such as nonlinear fluorescence microscopy.

Saturated hydrocarbons, including linear, branched, and cyclic alkanes, are known to fluoresce when excited in the vacuum ultraviolet near 140–160 nm. These saturated hydrocarbons display emission from 200–240 nm, which could readily be transmitted by quartz optics. Vacuum ultraviolet excitation conditions are incompatible with biochemical and biophysical experiments because it is necessary to exclude oxygen which strongly absorbs below 250 nm. They also require the use of special optics which transmit the vacuum ultraviolet excitation. Lakowicz et al. have demonstrated that saturated alkanes can be excited with two-photon excitation allowing frequency domain fluorescence spectroscopic measurements.[86,89–91] Two-photon excitation of alkanes was accomplished by using the pulse train from a cavity-dumped frequency-doubled R6G dye laser at 298–300 nm, with the light focused on a $\sim$10 μm diameter spot. They were able to recover two-photon excited fluorescence intensity decay traces from saturated alkanes such as the cyclic alkanes cyclohexane and methylcyclohexane,[89] the linear alkane tetradecane,[90] and fully saturated cholestane.[91] In these studies, they also showed that the alkane emission was quenched by alcohols, water, and oxygen.[86,89–91] By using the frequency domain technique to recover the excited state fluorescence intensity decay kinetics, they were able to suggest that the quenching of tetradecane by *n*-propanol is most likely to be collisional with a Stern–Volmer quenching constant of $37\,M^{-1}$, and an unquenched lifetime of 4.4 ns to result in a bimolecular quenching constant of $8.4 \times 10^9\,M^{-1}\,s^{-1}$. In the absence of *n*-propanol, the intensity decay was found to be a single exponential. The presence of *n*-propanol in tetradecane, however, resulted in a shift in the frequency response to higher frequencies, which indicates a decrease in the excited state fluorescence intensity decay time of tetradecane. An indication of the dynamic nature of the quenching observed from time-resolved fluorescence data was the modest multi- or complex exponential decays in the presence of *n*-propanol.[90] Such effects occur due to transit effects in diffusional quenching. Also, the value of the bimolecular quenching constant is near that expected for 100% efficient collisional quenching in a solvent of tetradecane's viscosity (2.18 cP). Additional quenching studies, using the known solubility of oxygen in liquid alkanes, yielded a bimolecular quenching constant for tetradecane and O_2 of $4.8 \times 10^{10}\,M^{-1}\,s^{-1}$, which was slightly above the diffusion-controlled limit.[86,90] The researchers attribute this value of bimolecular quenching constant to the fact that there could be absorption by oxygen at 200 nm, which could in effect increase the interaction distance for quenching due to energy transfer. An important implication of the sensitivity of alkane fluorescence to dissolved O_2 is that alkane fluorescence can provide an intrinsic probe of O_2 transport in membranes. Choletane and tetradecane, as well as the cyclic alkanes, were also found to be collisionally quenched by water.

Recently, Lakowicz et al.[92] observed fluorescence emission from 2,5-diphenyl-1,3,4-oxadiazole (PPD) resulting from two-photon excitation with two different wavelengths near 380 and 760 nm. The two-color two-photon (2C2P) induced emission was observed when the PPD sample was illuminated with both wavelengths, but only when the picosecond laser pulses were spatially and temporally overlapped. For 2C2P excitation, the time zero anisotropy was larger than possible for single-photon excitation and was consistent with collinear electronic transitions for both wavelengths. The intensity depended on the polarization of each beam in a manner consistent with collinear transitions. Their results demonstrate that 2C2P excitation can be readily observed with modern laser sources. This phenomenon is suggested to have numerous applications in the chemical and biomedical sciences, as a method for spatial localization of the measured volume.

11 SUMMARY AND FUTURE PROSPECTS

In this article, we have highlighted the applications of excited state fluorescence anisotropy and intensity decay measurements in several areas that we view as being of interest to the analytical community. Continued technological advances in excitation sources and detection electronics coupled with the development of long-lived red-NIR fluorescent dye chemistries are crucial for the practical application of time-resolved fluorescence to further applications as well as in facilitating transfer of this powerful technique to routine analysis (e.g. environmental, toxicological, clinical, and chemical process monitoring). Eventually, such advances in time-resolved fluorescence may result in a new generation of commercially viable clinical and medical devices (e.g. sensors) for use in the clinical laboratory or during office visits, at the patient's bedside, and even in home health care.

By way of example, measurement of excited state fluorescence intensity decay kinetics of saturated linear and cyclic alkanes following two- or multiphoton excitation opens up new avenues to probing molecular systems. Alkyl groups can be regarded as intrinsic fluorophores present in all macromolecules and emission from alkyl groups can be expected whenever they are in a nonpolar environment shielded from contact with the dipolar media. For instance, such aliphatic side chains of detergents and lipids may serve as intrinsic fluorescent probes of micelles and bilayers.

Finally, it should be noted that this article is by no means comprehensive. Within subsections, references were chosen to demonstrate particular recent areas of application or to highlight novel achievements. As such, they are in an academic sense representative of the types of research that have been conducted in this field in the 1990s.

ABBREVIATIONS AND ACRONYMS

ADC	Analog-to-Digital Converter
ANS	1,8-Anilino-8-naphthalenesulfonic acid
AOT	Aerosol OT
BME	β-Mercaptoethanol
BRE	Biorecognition Element
BSA-Ac	Acrylodan-labeled Bovine Serum Albumin
BSA-FL	Fluorescein-labeled Bovine Serum Albumin
BTBP	*N*,*N*′-bis-(2,5-Di-tert-butylphenyl)-3,4,9,10-perylenedicarboximide
CCD	Charge Coupled Device
CE	Capillary Electrophoresis
CMC	Critical Micelle Concentration
CW	Continuous Wave
FDB	Familial Defective Apolipoprotein B-100
FH	Familial Hypercholesterolemia
FLIM	Fluorescence Lifetime Imaging Microscopy
fwhm	Full Width At Half-maximum
HPLC	High-performance Liquid Chromatography
HPV	Human Papilloma Virus
HSA-Ac	Acrylodan-labeled Human Serum Albumin
LB	Langmuir–Blodgett
LED	Light Emitting Diode
MCA/PC	Multichannel Analyzer Personal Computer
MCPHA	Multichannel Pulse Height Analyzer
MEM	Maximum Entropy Method
MHF	Multiharmonic Fourier Transform
MLE	Maximum Likelihood Estimators
MPM/TIRF	Multifrequency Phase Modulation Total Internal Reflection Fluorescence
NIR	Near-infrared
NMR	Nuclear Magnetic Resonance
PAH	Polycyclic Aromatic Hydrocarbon
PCNMP	1-Phenyl-4-[(4-cyano-1-naphthyl)-methylene]piperidine
PCR	Polymerase Chain Reaction
PDT	Photodynamic Therapy
PMA	Poly(methyl acrylate)
PMMA	Poly(methyl methacrylate)
PMT	Photomultiplier Tube
PPD	2,5-Diphenyl-1,3,4-oxadiazole
PREWIF	Phase-resolved Evanescent Wave Induced Fluorescence
PS	Photosystem
R6G	Rhodamine 6G
SDS	Sodium Dodecyl Sulfate
SNAFL	Seminaphthofluoresceins
SNARF	Seminaphthorhodafluors
TAC	Time-to-Amplitude Convertor
TCSPC	Time Correlated Single Photon Counting
TIRF	Total Internal Reflection Fluorescence
TNS/PRODAN	Toluidinyl Naphthalene Sulfonic Acid/6-Propionyl-2-(*N*,*N*-dimethyl-amino)naphthalene
1-AN	*N*-phenylnaphthylamine
2,6-ANS	2-Anilinonaphthalene-6-sulfonic acid
2C2P	Two-color Two-photon

An overview is given of existing indirect detection methods of inorganic and organic anions in capillary zone electrophoresis (CZE). Kohlrausch's regulating function (KRF), used by several researchers to predict the detection sensitivity of ultraviolet (UV)-inactive analytes in CZE, is reviewed. Sensitive indirect photometric detection (IPD) of ionic compounds in CZE is largely governed by the value of the change in absorbance in a solute zone. This in turn depends on a transfer ratio (TR), ratio of the charge, and ratio of the electrophoretic mobility of the analyte and IPD reagent. The influence of other experimental parameters, such as pH, type and concentration of the absorbing electrolyte, detection wavelength, and absorption pathlength, on detection sensitivity are also critically discussed. An extensive part of this review deals with the separation of various classes of

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

ionic analytes using capillary zone electrophoresis/indirect photometric detection (CZE/IPD). Different approaches for simultaneous separation and indirect detection of nonabsorbing anions and cations are evaluated. From this evaluation, some rules of thumb as to when these approaches will be most effective are drawn. In addition, indirect fluorescence detection (IFD) in CZE and micellar electrokinetic chromatography (MEKC) are reviewed and possible application areas are highlighted. Some recent developments in other indirect detection modes, such as indirect chemiluminescence detection (ICLD) and indirect conductivity detection (ICD), are outlined.

1 INTRODUCTION

Direct detection employed in capillary electrophoresis (CE) refers to a situation where the eluent or electrolyte has a lower value of the measured physical property (i.e. absorbance, fluorescence, chemiluminescence, conductivity, amperometry), whereas indirect detection refers to a reverse condition. These two situations are shown schematically in Figure 1 for photometric detection. Indirect detection methods have been used in both ion chromatography (IC) and CE for mostly ionic species whose structure lacks the measured physical property for direct detection. These detection methods are universal in applicability and can be used with all detectors that are normally used to measure the analyte signal in a direct detection mode. Thus, indirect detection is applied to a wide variety of compounds without the need for pre- and postcolumn derivatization.

Figure 1 Comparsion of IPD (a) and direct photometric detection (b) in CE.

The first report dealing with the use of indirect detection in CZE for the analysis of ionic species was demonstrated more than 10 years ago by Hjerten et al.[1] This was followed by a report by Foret et al.[2] in 1989. Currently, it is an active area of research in CE for a variety of ionic compounds. Accordingly, this article provides a critical review dealing with the IPD and IFD methods of ionic species separated by CZE. All publications that have appeared in abstracted journals up until April 1999 are summarized. In addition, IFD of neutral species after their separation by MEKC is discussed. Only three communications on indirect chemiluminescence and three on indirect electrochemical (amperometry, conductivity) detection have been published, to my knowledge, since the beginning of 1990; therefore these indirect detection modes are discussed briefly.

1.1 Indirect Photometric Detection in Capillary Zone Electrophoresis

The real interest in the use of CZE with IPD, especially for inorganic ion analysis, started with the work of Jones et al. in the early 1990s.[3–8] At present, this is the most popular indirect detection mode in CZE analysis of a variety of inorganic and organic ions, and is discussed comprehensively in recent review articles.[9–13]

1.2 Theory and Operating Principle

In CZE, indirect absorbance detection (also known as IPD) has been used for ionic species whose structure lacks the absorbance properties for direct detection. The key element for IPD in CE is to maintain a large continuous background absorbance signal at the UV detector by employing a chromophoric ionic species (an ion with the same charge as the analyte) in the carrier electrolyte. If the concentration of this light-absorbing species remains constant in the electrical double layer in the CE column, a steady level of background absorbance translated as a stable baseline is displayed on the electropheretogram. When a non-UV-detectable ionic species passes the detection window, charge displacement of the chromophoric ion leads to a quantifiable decrease in the background absorbance. This translates to a negative peak; however, leads on the data acquisition system can be

switched to record signals as a positive peak. Similarly to IC, sensitive IPD of ionic species is possible in CZE mode because of the charge displacement that occurs in the electrical double layer of the bare fused-silica capillary. However, in CZE this charge displacement is enforced not by the ion-exchange groups as in IC, but by a fixed and oppositely migrating flux of counterions and by the requirement of electroneutrality.

1.3 Detector Response Equation

The concentration limit of detection (C_{LOD}), in moles per liter, for a nonabsorbing analyte detected using IPD can be expressed as a function of the concentration of the UV-absorbing species (C_M), the TR, and the dynamic reserve (DR), according to Equation (1):[14,15]

$$C_{LOD} = \frac{C_M}{DR \bullet TR} = \frac{N_{BL}}{TR \bullet \varepsilon l} \quad (1)$$

where N_{BL} is the baseline noise, ε is the molar absorptivity of the IPD reagent, and l is the pathlength of the detection cell. The DR is defined as the ability to measure a small change on the top of a large signal, and is equal to the ratio of the background absorbance to noise. The TR is defined as the number of moles of the IPD reagent displaced by one mole of the analyte. For example, TR values of 1 and 2 are possible when respective ions Cl^- and SO_4^{2-} are displaced by naphthalenemonosulfonate (NMS). Briefly, the TR predicts that, everything else being the same, the molar sensitivity of divalent ions is going to be twice that for monovalent ions. However, in reality a mobility match in CZE can offset such effects. Equation (1) also predicts that C_{LOD} can be improved by reducing C_M or by increasing the DR. Because the DR is also related to C_M, decreasing the concentration of the absorbing species (IPD reagents) will not necessarily improve the limit of detection (LOD). This is because the DR is also decreased, and electrophoretic dispersion in CZE can result in a poor LOD for nonabsorbing analytes. Hence, improving C_{LOD} often requires maximizing the DR by either reducing the background noise or increasing the background absorbance of the IPD reagent. Nevertheless, it can be concluded that all three parameters (C_M, DR and TR) of Equation (1) are not necessarily independent and an operator needs to optimize them to achieve the best possible detection limits. It is worth mentioning that C_{LOD} values for IPD of around 10^{-4}–10^{-5} M are routinely achieved in CZE.[16] The best C_{LOD} in IPD is obtained using a double-beam laser-induced diode detection, for which the C_{LOD} is about 10^{-7} M.[17] These systems typically reduce the noise level by an order of magnitude.

1.4 The Transfer Ratio and Kohlrausch's Regulating Function

As discussed earlier, the extent of displacement of the light-absorbing co-ion by the analyte is known as the TR. According to Equation (1), C_{LOD} is inversely proportional to the TR. Thus, a higher value of TR results in a large analyte peak area and a decrease in the C_{LOD} term. In addition, Equation (1) predicts that a TR between a singly charged analyte and the IPD co-ion would be unity. This means that peak areas for analyte ions of the same charge and concentration should be similar, which enables one to perform a universal calibration. However, Ackerman et al. called attention to the fact that a nonlinear relationship existed between peak areas and effective mobilities.[18] These researchers explained their results by considering KRF, also abbreviated as "w". This function w is generally written according to Equation (2):

$$w = \frac{C_i Z_i}{\mu_i} = \text{Constant} \quad (2)$$

where Z_i represents the absolute charges, μ_i the absolute values of effective mobility, and C_i the ionic concentrations of all ionic species. In addition, note that negative ions have negative μ and z values, whereas positive ions have positive μ and z values.

After the sample ion B is injected and the voltage is applied, a volume element of the capillary, which is originally filled with IPD reagent AC (A = UV-absorbing co-ion; C = non-UV-absorbing counterion) at a concentration C_A, will consist of a mixture of both co-ion A and the solute ion B for a while. However, the original situation will be restored very soon. Ackerman et al.[18] gave the expression shown in Equation (3) for the migrating sample ions in this case:

$$C_A^C = C_A^S + C_B^S k_B \quad (3)$$

The superscripts C and S in Equation (3) refer to the concentrations of the IPD electrolyte zone and the solute zone respectively. According to Nielen,[19] Cousins et al.,[20] Buchberger et al.,[12] and Klampfl et al.,[21] Equation (2) can be verified from Kohlrausch theory according to Equation (4):

$$k_B = TR = \frac{Z_B \mu_A (\mu_B + \mu_C)}{Z_A \mu_B (\mu_A + \mu_C)} \quad (4)$$

where k_B is referred to as the TR (also called the response factor); Z_A and Z_B represent absolute charges on analyte and the IPD co-ion A, respectively; μ_A, μ_B, and μ_C refer to the effective electrophoretic mobility of the IPD co-ion (i.e. ions of the same charge as that of the analyte) A, analyte ion B, and the nonabsorbing counterion (i.e.

ions of opposite charge to that of the analyte ion) C. The absorbances of the IPD ion (A^C) and the sample ion (A^S) can be written in accordance with Beer's law, as shown by Equations (5) and (6), respectively:

$$A^C = \varepsilon_A C_A^C l \quad (5)$$

$$A^S = \varepsilon_A C_A^S l + \varepsilon_B C_B^S l \quad (6)$$

From Equation (3), the UV signal generated as a change in background absorbance (ΔA) can be shown according to Equation (7):

$$\Delta A = A^C - A^S = C_B^S l(\varepsilon_A k_B - \varepsilon_B) \quad (7)$$

For non-UV-absorbing sample ions, $\varepsilon_B = 0$. Substituting for the TR from Equation (4), Equation (8) was derived:[12]

$$\Delta A = C_B^S l \varepsilon_A \frac{Z_B \mu_A(\mu_B + \mu_C)}{Z_A \mu_B(\mu_A + \mu_C)} \quad (8)$$

An important characteristic of Equation (8) indicates that, in an IPD system, the value of ΔA in a solute zone is proportional to the value of the TR (also known as the response factor, k_B), the ratio of the charge of the solute and the light-absorbing electrolyte ion, as well as the concentration of the solute ion. Hence, the values of ΔA (i.e. the detection sensitivities) for solutes with identical charges and concentrations can be determined by the values of the response factors. The value of ΔA is negative (i.e. analytes detected as negative peaks) if the running buffer with co-ion A is being used as a light-absorbing ion. In contrast, ΔA can be either positive or negative depending on the relative mobility of a solute to the nonabsorbing counterion in a system; and absorbing co-ion as the IPD reagent. Additionally, Equation (8) also indicates that when the mobility of the counterion (μ_C) is higher than the mobility of the solute (μ_B), ΔA will acquire a positive value; and a negative value when μ_C is lower than μ_B. Furthermore, when a solute ion has the same mobility as the co-ion (which is also a light-absorbing ion), equivalent-per-equivalent exchange can be expected. This charge displacement process improves the peak shape and increases the TR, which in turn provides a better LOD.

A literature survey indicates that several researchers have tested the validity of Equation (8). Nielen[19] first applied this equation to calculate the response factors of alkylsulfates using veronal as the IPD co-ion. He found the response factors of alkyl sulfates to be consistent with the trend predicted in Equation (8). Cousin et al.[20] recently determined the TR values for several inorganic anions using chromate, pyromellitate, trimellitate, phthalate and benzoate as IPD reagents. Comparison of TR values for these five reagents indicated that chromate is the best IPD reagent for high-mobility inorganic anions. However, the fit of the experimental data to the calculated data using Equation (8) was poor. Very recently, Doble et al.[22] observed that the agreement between experimental and theoretical values of TR can be improved if the IPD reagent is free of any interfering co-ions. For example, reformulating the electroosmotic flow modifier (i.e. addition of a tetradecyl-ammonium hydroxide instead of tetradecylammonium bromide) to the IPD electrolyte is beneficial because the hydroxide co-anions are utilized by the buffer.

2 FACTORS INFLUENCING INDIRECT PHOTOMETRIC DETECTION SENSITIVITIES

Theoretical considerations suggest that optimal sensitivity in IPD can be achieved if several conditions are fulfilled. First, the light-absorbing reagent should have a large molar absorptivity and an effective mobility that closely match those of the analyte ions. Second, the concentration of the IPD reagent and type and concentration of the nonabsorbing background electrolyte should be carefully selected. This is because high sensitivity is obtained only if the visualization co-ion is displaced by the analyte ion. Third, the pH of the light-absorbing electrolyte should be such that it minimizes the contribution of non-UV-absorbing H^+ and OH^- ions during the charge displacement process. For example, at very high pH (pH > 12.1), which is required for the ionization of weakly acidic compounds (e.g. sugars), the signal-to-noise ratio (S/N) in IPD drops sharply.[23] Fourth, choice of appropriate detection wavelength, low background noise and a long absorption pathlength are also desirable for sensitive detection.

2.1 Molar Absorptivity of the Indirect Photometric Detection Reagent

According to Equation (1), increasing the molar absorptivity ε of the IPD reagent increases the DR. The advantages of a high-ε reagent become apparent as one tries to decrease the C_M, resulting in improved detection limits. On the other hand, to obtain full benefit of a high-ε reagent care must be taken to match its mobility to the sample ion. A series of publications dealing with IPD in CZE has considered a high-ε reagent for optimum sensitivity.[2,5,20,24–31] For example, using sorbate (a high-ε reagent) instead of a benzoate (a low-ε reagent), Foret et al.[2] achieved a significantly (ca. 50 times) lower LOD. Shamsi and Danielson[24] investigated a series of

ribonucleotide reagents for the separation of polyphosphates (P_n) and polyphosphonates (RP_n). Best detection limits for these phosphorus-containing anions were obtained with adenosine 5′-monophosphate (AMP). This reagent provided the highest ε and closest mobility match for P_n and RP_n. Similar results were obtained by Beck and Engelhardt[25] and Weston et al.[26] when comparing a series of cationic IPD reagents for the separation and IPD of inorganic and organic cations. To extend the versatility of IPD reagents in the visible region, Mala et al.[27] investigated methyl green and chlorophenol red as IPD electrolytes for analysis of cations and anions, respectively. These dyes possess ε values an order of magnitude higher than conventional light-absorbing reagents such as chromate or phthalate. However, the reported LOD was not significantly better than those obtained with conventional reagents. Probably the presence of nonabsorbing co-ions competed with absorbing co-ions in the charge displacement, resulting in a less pronounced effect on the sensitivity of IPD.

2.2 Mobility of the Indirect Photometric Detection Reagent

As the sensitivity in IPD is governed by the ε of the carrier electrolyte, so too are its charge and electrophoretic mobility. Mikkers et al.[32,33] were the first to discuss the rules governing the effect of electrophoretic migration on the analyte zone concentration distribution using a nondiffusional model derived from KRF. According to this rule, symmetrical peaks are obtained only when the electrolyte co-ions have a mobility similar to that of the analytes. Electrolyte ions that have a slower mobility than the analytes will exhibit fronting peaks. In contrast, electrolyte co-ions with faster mobility than the analytes result in tailing peaks. Examples of the aforementioned rule were illustrated by Jones and Jandik[34] using three IPD electrolytes: chromate (high mobility), phthalate (intermediate mobility), and *p*-hydroxybenzoate (low mobility). Figure 2 shows the peak shapes of anions using these three IPD electrolytes. Note that the mobility for each IPD electrolyte is indicated by an arrow and represents the region that results in the most symmetrical peak shapes for analyte ions. Thus, the peak shapes in Figure 2 indicate that chromate has a mobility close to inorganic anions (peaks 1 and 2), phthalate has a mobility close to the carboxylates (peaks 3–5), and *p*-hydroxybenzoate has a mobility close to short-chain linear alkanesulfonates (peaks 6 and 7).

Shamsi and Danielson[35] used naphthalenesulfonates as IPD electrolytes and investigated the peak shapes for inorganic anions, organic acids and long-chain aliphatic sulfonates and sulfates. Figure 3 shows electropherograms of a standard mixture of seven common inorganic anions with singly charged NMS, doubly charged

Figure 2 Comparison of the peak symmetry for high-mobility (a), intermediate-mobility (b) and low-mobility (c) electrolytes for CZE analysis of anions. Peaks 1 and 2 symbolize inorganic anions; peaks 3–5 represent short-chain carboxylates; and peaks 6 and 7 represent short-chain alkanesulfonates. Chromate (high mobility), phthalate (intermediate mobility), and *p*-hydroxybenzoate (low mobility) are examples of the IPD co-ions.

Figure 3 Comparison of naphthalenesulfonate electrolytes for the separation of seven common inorganic anions. The electrolyte consisted of 4 mM NMS, NDS or NTS in 100 mM H_3BO_3, 5 mM $Na_2B_4O_7$, 2 mM diethylenetriamine (DETA), pH 8 buffer. Peak identification: 10 ppm each of (1) bromide, (2) chloride, (3) nitrite, (4) nitrate, (5) sulfate, (6) fluoride, and (7) orthophosphate. Vacuum injection for 3 s, −30 kV applied for separation, and current = 16–18 μA. IPD at 274, 288, and 284 nm, respectively. (Reproduced with permission from Shamsi and Danielson.[35] Copyright 1994 American Chemical Society.)

Figure 4 Comparison of naphthalenesulfonate electrolytes for the separation of alkyl sulfates. Peak identification: 20 ppm each of (1) C_{14} SO_4^-, (2) C_{12} SO_4^-, (3) C_{10} SO_4^-, (4) C_8 SO_4^-, (5) C_6 SO_4^-, and (6) C_4 SO_4^-. The electrolyte consisted of 5 mM NMS, NDS or NTS in 100 mM H_3BO_3, 5 mM $Na_2B_4O_7$, pH 8 buffer. Vacuum injection: 4 s for NMS and 5 s for NDS and NTS; +30 kV applied for separation; current = 8–10 μA. (Reproduced with permission from Shamsi and Danielson.[35] Copyright 1994 American Chemical Society.)

Figure 5 Separation of inorganic cations with imidazole/α-hydroxybutyric acid (α-HIBA) electrolyte. Conditions: 5 mM imidazole/6.5 mM α-HIBA/2 mM 18-crown-6, pH 4.5; 75 mm i.d. × 60 cm capillary; 30-s injection; 20 kV; UV detection at 214 nm. Sample 1 μg mL^{-1} of each cation. naphthalenedisulfonate (NDS), and triply charged naphthalenetrisulfonate (NTS) electrolytes. Although all three electropherograms were run under similar conditions, the analyte peak shapes were very different. With NMS, poor sensitivity and peak fronting were evident, whereas NDS and NTS electrolytes provided almost equally good peak shapes for all seven anions. Note that for the NDS electrolyte, the orthophosphate peak becomes very symmetrical, whereas fluoride gives an excellent peak shape with NTS. These differences in peak shapes for orthophosphate and fluoride are consistent with their very close mobility match with NDS and NTS respectively. The authors clearly showed that although NDS and NTS provided good electrophoretic separations, NMS, having a much lower electrophoretic mobility than the inorganic anions, was not a suitable electrolyte for this mixture. In contrast, the reverse was found to be true when the same group of electrolytes were compared for the separation of aliphatic anionic surfactants (C_4–C_{14} SO_4^-). For C_4–C_{14} SO_4^-, NMS was found to be the best electrolyte, whereas NTS, because of its very high mobility, gives an inadequate separation for this particular mixture (Figure 4). In general, NDS showed much wider applicability (i.e. reasonable peak shapes for high-mobility inorganic anions, intermediate-mobility organic acids, and low-mobility long-chain aliphatic anionic surfactants) compared with NMS or NTS. Nevertheless, these studies clearly indicate that the selection of a UV-absorbing electrolyte in IPD must include the consideration of achieving not only high molar absorptivity, but one with a close mobility match to the sample components.

As in the case of anions, several studies have shown that mobility matching is also important for the IPD of cationic solutes.[36] An electropherogram is shown in Figure 5 for the separation of five inorganic cations and ammonium ions using imidazole as the IPD reagent. In this electropherogram, ammonium and potassium exhibit fronting whereas lithium exhibits tailing. Additionally, calcium, sodium, and magnesium show no peak asymmetry, indicating that the imidazole has a mobility close to these cations.

Peak shape is also related to the ratio of the conductivities of the analyte and the running electrolyte. According to Hjerten,[37] the absolute difference in conductivity depends on two factors: the difference in mobility between an electrolyte and the analyte ion; and the total concentration of the analyte. This dependence is shown by Equation (9):

$$\Delta\kappa = \frac{c_{\text{analyte}}}{\mu_{\text{analyte}}}(\mu_{\text{co-ion}} - \mu_{\text{analyte}})(\mu_{\text{counterion}} - \mu_{\text{analyte}}) \quad (9)$$

where $\Delta\kappa$ is described as the conductivity difference between a sample zone and the carrier electrolyte, c_{analyte} and μ_{analyte} are the concentration and mobility of the analyte respectively, and $\mu_{\text{co-ion}}$ and $\mu_{\text{counterion}}$ are the respective electrophoretic mobilities of the co-ion and the counterion. It is worth noting that the electrophoretic mobility of a cation usually has a positive sign, whereas the electrophoretic mobility of anions has a negative sign.

Figure 6 S/Ns of some inorganic anions as a function of UV-absorbing electrolyte (NDS or NTS) concentration prepared in a 100 mM H_3BO_3, 5 mM $Na_2B_4O_7$ 2 mM diethylenetriamine, pH 8 buffer. (Reproduced with permission from Shamsi.[52])

2.3 Concentration of the Indirect Photometric Detection Reagent

The concentration of the IPD electrolyte co-ion is also an important consideration, for two major reasons. First, it is the ratio of the conductivities of the sample and the electrolyte that will control the peak shape; in general, peak efficiency and resolution increase with increasing ratio of the light-absorbing carrier electrolyte concentration to sample concentration. Second, the absorbance detector used in IPD mode shows a linear response range up to 0.20 AU, therefore the maximum concentration of the IPD electrolyte that can be used is the concentration that will give a background absorbance of <0.20 AU. Recent studies by Shamsi et al. indicated that the background absorbance inside the fused-silica capillary can be linear up to ca. 0.5 AU, a value dependent on both the type of IPD electrolyte and the detector optics.[24] The same authors have also studied the effect of increasing the concentration of NDS or NTS reagent on the S/N of some inorganic anions. As shown in Figure 6, sensitivity first tends to increase with the increase in NDS or NTS concentration between 1 and 4 mM, providing sharper peaks and better resolution. With a further increase in concentration, i.e. >4 mM NDS or NTS, a downward trend in S/N is evident. This decrease in S/N is obviously due to an increase in the magnitude of noise, which increases proportionally with increasing concentration of UV-absorbing electrolytes. In addition, the linear response range for the nonchromophoric analytes is strongly influenced by the IPD electrolyte concentration. The use of a higher concentration of IPD reagents will extend the upper linear range of the analyte ion, although at a high IPD electrolyte concentration the background noise and Joule heating also increase, thus decreasing the sensitivity of IPD. In general, most electrolytes used in IPD have concentrations in the range 1–10 mM. This means three orders of magnitude in linearity for the analyte ion. It should be noted that in IPD the running electrolyte concentrations are ca. 10 times less than those employed in CZE with direct UV detection. Therefore, peak distortion due to a mobility mismatch is more critical with indirect than with direct photometric detection.

2.4 Type and Concentration of the Nonabsorbing Buffer

One approach that optimizes electrophoretic separation and IPD of inorganic anions is the use of nonabsorbing co-anionic buffers such as borate,[24,35,38–40] acetate,[41] phosphate,[42] and carbonate.[43] Obvious advantages of these buffer co-anions are high reproducibility, sharper peaks, and rugged separations. In practice, baseline noise at higher ionic strength of the co-anionic buffer results in reduced S/N due to dilution of the zones of the light-absorbing reagent by nonabsorbing co-anions. Moreover, the presence of these co-anionic buffers leads to system peaks that may interfere in the analysis of some inorganic anions.[24,35]

The migration time and S/N of some inorganic anions as a function of borate ($H_3BO_3/Na_2B_4O_7$) concentration from 20 to 200 mM has little effect on the migration of anions. However, increasing the concentration of the same buffer anions improved the detection limits by a factor of 2 for low-mobility inorganic anions (e.g. phosphate, fluoride) (Figure 7). In contrast, little effect on

Figure 7 S/Ns of some inorganic anions as a function of borate concentration prepared in a 3 mM NTS, 2 mM diethylenetriamine, pH 8 buffer. (Reproduced with permission from Shamsi.[52])

the S/N of high-mobility inorganic anions (e.g. bromide, chloride, nitrite, and nitrate) was seen. Probably, the mobility of borate anion matches the former more closely than the latter group of anions.

A second approach entails the use of nonabsorbing countercations such as Tris[44–47] and triethanolamine.[48–50] The running CZE buffers are generally prepared by titration of the acid form of IPD electrolyte with the buffering base. Because these running CZE buffers consist of a single co-anion, the charge displacement process is simplified and the S/N remains unaffected.

2.5 pH of the Indirect Photometric Detection Reagent

Similarly to ion-exchange chromatography, IPD in CZE is also sensitive to pH extremes. The CZE separations of inorganic cations are mostly performed over the range 3–5. In contrast, anionic CZE separations are rarely obtained at a pH of <7.0. The reason for this is that these inorganic cations and anions, as well as the capillary surface, have different properties at different pH values. For example, at high pH, CZE separations of some metal cations (e.g. transition metals, alkaline earths) are not feasible, due to precipitate formation and interaction of these cations with the negative charge of the fused-silica capillary. Moreover, aromatic bases that are commonly used as IPD reagents for cation separations have pK_a values in the acidic pH range. This means that they are not appreciably ionized at neutral to basic pH values. In view of this, the pH of the running electrolyte should be sufficiently low so that IPD reagent exists as cations with sufficiently high mobility to match the mobility of fast-moving inorganic cations. On the other hand, the selection of pH for the CZE separation of inorganic anions is not as critical. This is because the majority of the inorganic anions are strong acids and hence are completely ionized in neutral to alkaline pH conditions. One exception is the weakly ionized solute (e.g. carbohydrates), which requires a pH approaching 12 to have any appreciable fraction in the anionic form. When choosing pH > 12, the concentration of the hydroxide ions is no longer negligible relative to the concentration of the IPD electrolyte. Consequently, a decrease in TR generally reduces the IPD signal.

Figure 8 Impact of pH value on sensitivity. Electrolyte is 6 mM sorbate; fused-silica capillary = 122 × 100 cm, 50 μm i.d; current is 6, 8, 13, 17, 20, and 24 μA at pH 11.58, 11.87, 12.08, 12.22, 12.33, and 12.42, respectively; voltage is +28 kV; separation temperature = 30 °C; UV detection at 256 nm; sampling by vacuum injection for 1 s; sample is 12.5 mM mannose. (Reproduced with permission from Jandik and Bonn.[16])

Figure 9 The influence of pH of the background electrolyte solution: 10 mM phthalic acid. The pH values tested were: (a) pH 4.3; (b) pH 6.5; (c) pH 7.7; (d) pH 9.2. Injection time was 2 s. The concentration of the anions was 50 μM each. Peak identification: a = bromide; b = chloride; c = nitrate; d = sulfate. (Reproduced with permission from Ma and Zhang.[31])

Vorndran et al.[51] first described the use of sorbate as the IPD reagent for the analysis of carbohydrates. A rather simple electrolyte system containing 6 mM sorbate adjusted to pH 12.1 with sodium hydroxide permits the separation of 11 carbohydrates in ca. 20 min. Although resolution of carbohydrates improved with rising pH, the sensitivity of detection decreased considerably above pH 12.1 (Figure 8). Ma et al.[31] investigated the influ-

Figure 10 Effect of electrolyte pH on the separation of 12 P_n and RP_n. Electrolyte consisted of 5 mM AMP and 2 mM DETA adjusted to various pH values with 1 mM NaOH. Vacuum injection for 15 s; −30 kV applied for separation; current = 6–13 μA. Peak identification: 5–10 mg L^{-1} each of: (1) 21 μmol L^{-1} cyclic P_3; (2) 51 μmol L^{-1} P_1 fluorophosphate; (3) 62 μmol L^{-1} P_1 phosphite; (4) 52 μmol L^{-1} P_1 phosphate; (5) 78 μmol L^{-1} P_1 hypophosphite; (6) 49 μmol L^{-1} 1-hydroxyethylidene-1,1-diphosphonic acid (HEDP); (7) 21 μmol L^{-1} cyclic P_6; (8) 57 μmol L^{-1} P_2 phosphate; (9) 21 μmol L^{-1} hexamethylenediaminetetra(methylenephosphonic acid) (HDTMP); (10) 34 μmol L^{-1} aminotri(methylenephosphonic acid) (ATMP); (11) 23 μmol L^{-1} ethylenediaminetetra(methylenephosphonic acid) (EDTMP); (12) 18 μmol L^{-1} diethylenetriaminepenta(methylenephosphonic acid) (DETPMP). (Reproduced with permission from Shamsi and Danielson.[24] Copyright 1995 American Chemical Society.)

ence of the pH of the phthalate electrolyte on the separation and IPD of four inorganic anions (bromide, chloride, nitrate, and sulfate). At low pH (i.e. pH 4.3), phthalate electrolyte being singly charged has lower electrophoretic mobility, resulting in poor S/N for the high-mobility inorganic anions (Figure 9, spectrum a). Increasing the pH to 6.5 fully ionized the phthalate electrolyte and improved the S/N (Figure 9, spectrum b). Further increase in pH value enhanced the overall resolution of the anions (Figure 9, spectra c and d), but at the expense of longer migration times and peak broadening.

Shamsi and Danielson[24] studied the effect of pH on the detection limits of phosphorus-containing anions using AMP as the IPD reagent. The four electropherograms shown in Figure 10 illustrate that both the S/N and the migration time of P_n and RP_n decrease as the pH is increased from 6.30 to 8.30. However, the overall increase in mobility of these anions is not as much as one would have expected. This is because electroosmotic flow and electrophoretic vectors oppose each other. The increase in baseline noise at pH 8.30 was found to be caused by dilution of the AMP zones by the nonabsorbing co-anions (hydroxide and borate anions). Excessive heating due to an increase in current from 6 μA at a pH of 6.80 to 13 μA at a pH of 8.30 resulted in greater mobility of hydroxide ions, and consequently an increase in the baseline noise.

Shamsi and Danielson also compared the theoretical and experimentally determined detection limits of 12 P_n and RP_n. The experimentally determined TR (ΔT) was compared with the TR expected on the basis of an equivalent-to-equivalent exchange between the electrolyte and analyte ions. It was shown that there can be situations in which a large TR value for some analytes is less important than a small ΔT value with respect to the experimental detection limits. Several examples of this situation are shown in Table 1. At a pH of 7.80, P_2 phosphate, HDTMP, ATMP, EDTMP, and DETPMP have more favorable ΔT and TR values than P_1 phosphite,

Table 1 Comparison of theoretical and experimentally determined detection limits using AMP as electrolyte (effective charges of −1.8 and −2.0 at pH 6.8 and 7.8, respectively, calculated using equation from Haddad and Jackson[198])

Analyte	Effective charge		ΔT[a,b]		TR[c]		Calc. LOD × 10^6 (M)[d]		Exp. LOD × 10^6 (M)

[a] Measured with respect to nitrate.
[b] ΔT = Relative migration time of AMP − Relative migration time of analyte.
[c] TR = Effective charge of analyte/Effective charge of AMP.[24]
[d] Calculated using Equation (1).

Figure 11 Effect of wavelength on sensitivity and direction of photometric signal for (a–c) inorganic anions and (d–f) organic acids. Peak identification: (a–c) as Figure 3; (d–f) 1 = oxalate, 2 = malonate, 3 = formate, 4 = fumarate, 5 = maleate, 6 = succinate, 7 = malate, 8 = citrate, and 9 = tartrate. (Reproduced with permission from Shamsi.[52])

P_1 phosphate, or P_1 hypophosphite. For this reason, the detection limits of the former group of analytes were 2–5 times better then the latter. However, at a lower pH of 6.80 the differences in ΔT and the experimental detection limits between these two groups of analytes were not great. In general, the authors found that a low pH improves the sensitivity but at the same time increases the ΔT values for P_n and RP_n. Because of these two competing factors, the detection limits of some phosphorus anions, such as P_1 phosphate or P_1 hypophosphite, were improved whereas the detection limits of DETPMP became worse. On the other hand, there was not much change in the detectability of HDTMP, ATMP, and EDTMP at pH 6.80 compared to pH 7.80.

2.6 Effect of Detection Wavelength

Another method of optimizing sensitivity is the choice of an appropriate detection wavelength. The largest signal generated for IPD is found where the light-absorbing reagent absorbs most strongly and the analytes absorb the least. In general, most inorganic cations have no UV absorbance at any wavelength. Hence, IPD reagents for inorganic cations can be selected that have strong UV absorbance at wavelengths as low as 185 nm. Figure 11 shows the effect of wavelength on sensitivity and direction of the photometric signal for seven common inorganic anions and organic acids at three different detector wavelengths using NTS as the IPD reagent. Although shorter wavelengths of 214 and 206 nm can improve sensitivity for some nonabsorbing analytes, a more universal detection (i.e. all peaks in one direction) is obtained at a longer wavelength of 284 nm for both inorganic anions and organic acids.[52] Although NTS does have another wavelength maximum at 234 nm, this wavelength was not utilized because the absorbance was outside the Beer's law working range. Analytes such as nitrite and nitrate, which are UV-absorbing at a wavelength of 214 nm, showed positive peaks but nitrite detectability was not improved because the absorption difference between nitrite and NTS is not great at this wavelength. In contrast, the sensitivity of detection of bromide, nitrite and nitrate can be improved by direct UV detection at a wavelength of 206 nm. In addition, organic acids such as maleate can be detected directly at 206 nm.

Optimizing the sensitivity for inorganic anions using chromate as an IPD electrolyte at different wavelengths has also been studied by Jones in detail.[53] This

Table 2 Peak height ratio with respect to 254 nm for nine different wavelengths using a mixture of 11 inorganic anions and detection limits defined as 3 × noise (in ppm)[a]

No.	Wavelength (nm)								
	185	214	229	254	313	365	405	436	546

[a] Reproduced by permission from Jones.[53] (Copyright 1993 Elsevier Science N.V.) A negative number indicates that the analyte is more absorbing than the electrolyte. The terms dl and np stand for detection limit and no peak, respectively.

electrolyte provides the strongest background signal at 185 nm, followed by the second and third strongest background signals at 365 nm and 254 nm respectively. As shown in Table 2, 185 nm provided the largest peak height ratio for 9 of 11 inorganic anions, whereas 365 nm had the second and 254 nm had the third largest peak height ratio for at least seven inorganic anions. However, the largest peak height does not necessarily provide the lowest detection limits. This is because the lamp energy can also influence the detector performance. Higher-energy lamps generate more photons per unit time, thus reducing the shot noise. A comparison of lamp output energy at 185, 254, and 365 nm indicated that the mercury lamp operated at 254 nm provided the highest photodiode current (ca. 1.55 nA) and thus the best detection limits for 11 inorganic anions (Table 2).

2.7 Effect of Background Noise

In general, the noise level observed in IPD is higher than in direct detection using the same instrument. Wang and Hartwick[47] were the first to study in detail the factors that influence the background noise in IPD. The authors found that the noise in IPD is generated from at least two different sources: the IPD reagent, and the detector electronics. Although the mechanism of noise produced from the IPD reagent was not clear, it appeared to be dependent on the concentration of the IPD reagent, the applied voltage, and the surface modification of the capillary. To improve the C_{LOD} in IPD, light-emitting diodes have been developed that provide excellent baseline stability and reduced noise level up to one order of magnitude.[54–56] However, these diodes require the use of IPD reagents that absorbs light in the visible region. Characterization of a suitable IPD electrolyte in the visible region is problematic for two major reasons: first, chromophores that have intense absorption in the visible region are large organic molecules with lower electrophoretic mobilities that do not match those of the analytes (e.g. high-mobility inorganic anions); and second, the adsorptive interactions of such molecules with the capillary cause baseline fluctuations. Thus, the actual C_{LOD} in the visible region with light-emitting diodes is no better than the conventional IPD in the UV region.

2.8 Effect of Absorption Pathlength

The influence of detection cell length, l, with the aim of increasing the background noise, has been investigated by several authors. Ma and Zhang.[31] studied the effect of increasing pathlength by comparing capillaries having different diameters. They observed that the detection limits were about the same when a capillary internal diameter was increased from 25 μm to 75 μm, but Joule heating increased with increasing capillary diameter, resulting in an increase in the background noise. This result is in agreement with the data published by Anderson et al.,[57] but is in contrast to the report by Steinar et al.[58] in which the S/N increased with an increase in capillary diameter from 10 μm to 1000 μm. Probably in the latter study the background noise level was not measured with the voltage on, and therefore the contribution of Joule heating to noise was insignificant. Weston et al. reported improvement in the IPD signal by a factor of approximately two using a capillary of extended pathlength.[26] A 75-μm capillary was extended to 300 μm by blowing a bubble at the detection window. This procedure is very useful because the contribution of Joule heating to the background noise is negligible due to the capillary diameter being unchanged for almost the entire capillary length.

3 DETERMINATION OF ANIONIC AND CATIONIC COMPOUNDS

Detection of nonchromophoric anions and cations in CZE is usually accomplished using anionic and cationic chromophoric reagents, respectively. Tables 3–10 list typical carrier electrolytes that are compatible for IPD of anionic and cationic solutes. These compounds can be classified into groups as shown and discussed below:

1. IPD of inorganic anions (Table 3);
2. IPD of inorganic cations (Table 4);
3. IPD of short-chain organic acids and amines (Table 5);
4. IPD of long-chain fatty acids (Table 6);
5. IPD of inorganic and organic phosphates (Table 7);
6. IPD of long-chain aliphatic anionic and cationic surfactants (Table 8);
7. IPD of carbohydrates (Table 9);
8. IPD of amino acids and phospholipids (Table 10).

3.1 Indirect Photometric Detection of Inorganic Anions

As discussed earlier, IPD was probably used for the first time in CZE by Hjerten et al. in 1987[1] and Foret et al. in 1989.[2] Although these publications addressed the CZE determination of some low-molecular-weight anionic species, a real breakthrough in the development of IPD in CZE was a consequence of the work of Jones and Jandik.[3–8] These researchers were the first to report the analysis of 36 inorganic and organic anions in ca. 3.0 min using a chromate as the IPD electrolyte and tetradecyltrimethylammonium bromide (TTAB) to reverse the electroosmotic flow (Figure 12).[8] Since that report, chromate has been the most widely used carrier

electrolyte for the analysis of inorganic anions (Table 3), for several important reasons. One is that chromate is a high-mobility anion that provides very symmetrical peak shapes for analysis of fast-moving inorganic solutes (e.g. bromide, chloride, nitrite, nitrate, sulfate, fluoride, and phosphate). In addition, this electrolyte possesses strong UV absorption over a broad (200–400 nm) range. The second reason is that detection using chromate is performed at 254 nm, which maximizes the largest possible number of anions to be detected universally, including those that are themselves UV-absorbing at low wavelengths. This is beneficial because most commercial CE instruments have a wide DR with low noise at 254 nm.

Table 3 Some typical examples of IPD in CE separation of inorganic anions

Analytes	Sample	IPD reagent	Electrolyte system	Detection λ (nm)	Refs.
Thiosulfate, bromide, chloride, sulfate, nitrite, nitrate, azide, molybdate, chlorite, tungstate, phosphite, monofluorophosphate, chlorate, carbonate, phosphate, fluoride	Standard mixture; Kraft black liquor; urine	Chromate	5 mM Sodium chromate, 0.4 mM OFM Anion-BT adjusted to pH 8	254	3, 6–8
Thiosulfate, bromide, chloride, sulfate, nitrite, nitrate, phosphate, fluoride	Standard mixture	Chromate	5 mM Sodium chromate, 0.5 mM TTAB, 5 mM boric acid, pH 8	254	49
Chloride, bromide, nitrite, sulfate, nitrate, fluoride, phosphate, carbonate	Standard mixture	Chromate	5 mM Sodium chromate, 3.5 mM tetradecyltrimethylammonium hydroxide, 10 mM CHES, pH 9	254	36
Bromide, chloride, nitrite, nitrate, sulfate, fluoride, phosphate	Standard mixture	Chromate	5 mM Sodium chromate, 0.14% (w/v) PDDPiCr	254	192
Thiosulfate, chloride, sulfate, sulfite, carbonate	Standard mixture	Chromate	5 mM Sodium chromate, 0.001% hexadimethrine bromide, 20% acetonitrile, pH 11	185	193
Arsenate, bromate, bromide, chlorate, chloride, fluoride, molybdate, nitrate, nitrite, perchlorate, sulfate, phosphate, tetrafluoroborate, thiocyanate, thiosulfate, tungstate	Standard mixture; tapwater; ground and surface water; steam flow; swimming-pool water	Pyromellitate	2.25 mM Pyromellitate, 6.5 mM sodium hydroxide, 1.6 mM triethylamine (TEA), 0.75 mM hexamethonium bromide or hydroxide	250	20, 29, 30, 49, 59, 196
Bromide, chloride, nitrate, fluoride, sulfate, phosphate		Pyromellitate	2.25 mM Pyromellitate, 6.5 mM sodium hydroxide, 1.6 mM TEA	250	194
Bromide, chloride, nitrite, nitrate, sulfate, fluoride, phosphate, dithionate, tetrathionate, thiocyanate, iodide, chlorite, bromate, chlorate, iodate, perchlorate, cyclic P_3	Standard mixture	NDS; NTS	4–8.3 mM NDS or NTS, 100 mM H_3BO_3/5 mM $Na_2B_4O_7$, 2 mM DETA, pH 8	288, 284, 214	35

Bromide, chloride, nitrate, sulfate	Standard mixture	*O*-Benzylbenzoic acid	20 mM *O*-Benzylbenzoic acid, pH 6.5	228	31
Chloride, fluoride, nitrite, nitrate, sulfate, phosphate, phosphite	Standard mixture; fermentation broths	2-Nitroso-1-naphthol-6-sulfonate; 1-nitroso-2-naphthol-3,6-disulfonate	0.5 mM 2-Nitroso-1-naphthol-6-disulfonate or 1-nitroso-2-naphthol-3,6-disulfonate, pH 8	254	63
Bromide chloride, nitrite, nitrate, sulfate, thiosulfate	Standard mixture	Vanadate	7.5 mM Sodium vanadate, pH 8	254, 226, 270	197
Chlorate, chloride, fluoride, nitrate, sulfate	Standard mixture	Permanganate	20 mM Permanganate, pH 7	635, 670	55
Bromide, chloride, nitrate, sulfate	Standard mixture	Chlorophenol red; indigo carmine	0.5 mM Chlorophenol red or indigo carmine, 5 mM Tris, pH 6 adjusted with acetic acid	635, 670	27
Sulfate, sulfide, tetrathionate, thiosulfate	Standard mixture	1,3-Benzene-disulfonate	3 mM 1,3-Benzenedisulfonic acid, 10 mM Tris, 0.5 mM DETA, pH 8.15	254, 214	29
Bromide, chloride, nitrate, sulfate	Standard mixture	2-Sulfobenzoic acid	20 mM 2-Sulfobenzoic acid, pH 6.5	228	31

CHES, 2-(*N*-cyclohexylamino)ethanesulfonic acid; PDDPiCr, poly(1,1-dimethyl-3,5-dimethylenepiperidinium) chromate.

Although the first recipe of chromate/TTAB electrolyte was very useful for IPD of many inorganic anions, this recipe has suffered from several problems. First, the electroosmotic flow modifier TTAB used in the chromate electrolyte was a bromide salt. Samples containing trace bromide levels induced a negative peak where bromide (generated from TTAB) normally migrates in the electropherogram. This negative peak not only decreased the bromide sensitivity but also caused problems with chloride integration. Second, the elution order of some inorganic anions (thiosulfate < bromide < chloride) was not very beneficial. A favorable elution order would be one in which chloride migrated first so that it could be used as a reference component. The benefit of this technique is easier peak identification based on the migration time ratio (migration time of analyte peak/migration time of the chloride peak). Additionally, referencing can also minimize drifts in the migration time due to changes in electroosmotic flow. Third, this recipe using the chromate electrolyte involved the electrolyte being prepared from the sodium salt and therefore unbuffered. It is well known that the use of an unbuffered electrolyte in CZE can cause electrolysis of water at the inlet and outlet vials.

To utilize better the benefits of chromate in IPD of inorganic anions, Mazzeo[36] has proposed reformulation of the chromate electrolyte. The author has reported the use of tetradecyltrimethylammonium hydroxide instead of TTAB. The conversion of TTAB to its hydroxide was accomplished by passing the former through an anion-exchange cartridge in the hydroxide form. The main problem with this procedure is the large excess of hydroxide ions introduced, resulting in a high-pH chromate. In such cases, it becomes necessary to reduce the pH with various organic acids (e.g. acetic acid or boric acid). However, a negative peak still appears in the electropherogram that corresponds to the migration time of the acid co-anion. Several reports have appeared describing the addition of low-mobility co-anionic buffers such as carbonate,[43] borate,[40,49,57] and CHES.[58] Because of the low mobility of the aforementioned co-anionic buffers, a negative system peak is observed in the electropherogram but is well removed from the high-mobility inorganic anions. Nevertheless, the addition of

Figure 12 Electropherogram (83-s section) of 36 anions. Peak identification and concentrations (ppm): 1 = thiosulfate (1.3); 2 = bromide (1.3); 3 = chloride (0.7); 4 = sulfate (1.3); 5 = nitrite (1.3); 6 = nitrate (1.3); 7 = molybdate (3.3); 8 = azide (1.3); 9 = tungstate (3.3); 10 = monofluorophosphate (1.3); 11 = chlorate (1.3); 12 = citrate (0.7); 13 = fluoride (0.3); 14 = formate (0.7); 15 = phosphate (1.3); 16 = phosphite (1.3); 17 = chlorite (1.3); 18 = glutarate (1.7); 19 = *o*-phthalate (0.7); 20 = galactarate (1.3); 21 = carbonate (1.3); 22 = acetate (1.3); 23 = chloroacetate (0.7); 24 = ethanesulfonate (1.3); 25 = propionate (1.3); 26 = propanesulfonate (1.3); 27 = D,L-aspartate (1.3); 28 = crotonate (1.3); 29 = butyrate (1.3); 30 = butanesulfonate (1.3); 31 = valerate (1.3); 32 = benzoate (1.3); 33 = L-glutamate (1.3); 34 = pentanesulfonate (1.7); 35 = D-gluconate (1.7); 36 = D-galacturonate (1.7). The electrolyte is 5 mM chromate and 0.4 mM OFM Anion-BT adjusted to pH 8.0. Applied potential is 30 kV (negative polarity); capillary dimensions are 60 cm (52 cm to detector) × 50 μm i.d. fused silica; indirect UV detection; injection by electropherogram at 1 kV for 15 s. (Reproduced with permission from Jones and Jandik.[8])

such buffering agents requires a careful pH optimization to prevent the interference of system peaks with analytes of interest. As suggested by Haddad,[10] a more attractive alternative to buffer the chromate electrolyte is to use a buffering countercation such as Tris or diethanolamine in the chromate electrolyte.

Pyromellitic acid (PMA; or 1,2,4,5-benzenetetracarboxylic acid) is another suitable IPD reagent for the analysis of high-mobility inorganic anions.[20,29,30,49,59] Although PMA offers higher molar absorptivity than chromate, the latter is still a preferred IPD reagent because of its excellent mobility match for the common inorganic anions. Mazzeo[36] has also reported improved resolution and better peak shapes with shorter analysis time for inorganic anions using chromate instead of PMA.

Recently, naphthalenesulfonate reagents have been characterized by Shamsi and Danielson for IPD of a large number of inorganic anions.[35] A comparison of NMS, NDS, and NTS revealed that NMS was the best electrolyte for aliphatic anionic surfactants, whereas NDS and NTS caused more efficient separation of inorganic anions (Figures 3 and 4). NDS, in particular, was found to be applicable for efficient CZE separation for a much wider analyte range. For example, NDS electrolyte provided successful IPD of all three classes of anions, namely inorganic anions, organic acids, and aliphatic anionic surfactants.

Several other IPD reagents, including phthalate,[20,29,31,39] trimellitate,[20,47,60–62] *o*-benzylbenzoic acid,[31] sulfobenzoic acid,[31] and 1-nitroso-2-naphthol-3,6-disulfonate,[63] have also been examined. However, these reagents provide sensitive IPD of only a few inorganic anions. As a general observation, it can be said that currently chromate, PMA, and NTS are the three most suitable IPD reagents for the CZE analysis of high-mobility inorganic anions.

3.2 Indirect Photometric Detection of Inorganic Cations

As evidenced by recent reviews, CZE with IPD has been widely used in the analysis of inorganic cations (Table 4) in various samples.[64,65] Unlike anion analysis, CZE separation of cations is easily obtained in the low pH range of 4–5 without modifying the capillary surface and without reversing the electroosmotic flow. Owing to small differences in the electrophoretic mobility of a metal cation, it has become quite common to include a neutral or anionic complexing agent in the IPD buffer to enhance cation selectivity. Short-chain mono-, di-, tri- and tetracarboxylic acids are the most popular complexing agents. Several authors have studied the use of α-HIBA, glycolic acid, lactic acid, tartaric acid, succinic acid, citric acid, ethylenediaminetetraacetic acid, and tropolone as complexants for the separation of metal cations. In addition, to resolve the potassium and ammonium peaks from one another, 18-crown-6 is generally added to the IPD electrolyte.

The use of imidazole as carrier electrolyte with IPD was proposed initially by Beck and Engelhardt[25] for both high-mobility alkali and alkaline earth metals, and has since been used by a number of authors.[66–68] The electrolyte imidazole is a high-mobility cation that shows sufficient UV absorbance to permit sensitive IPD at 214 nm. An example of the separation that can be achieved with 5 mM imidazole adjusted to pH 4.5 with sulfuric acid is shown in Figure 13. It is apparent that the elution order of the solute ions (e.g. Ba^{2+}, Ca^{2+}, Mg^{2+}) is influenced by their ability to complex sulfate. Detection limits (ca. 0.1 ppm) and linearity of response (0.5–10 ppm) were established and the method was applied for routine analysis of inorganic cations in apple vinegar. Lin et al. have determined the relative merits of using different complexant (α-HIBA, acetate, lactate, malonate, succinate, citrate) with 5 mM imidazole for CZE separation of alkali and alkaline earth

metals.[66] The authors noted that monoprotic acids (acetate, lactate, α-HIBA) showed the weakest complexation with divalent cationic solute, whereas the triprotic acid citrate showed the strongest. Yang[67] and Francois et al.[68] have also investigated imidazole as an IPD electrolyte but used 18-crown-6 as the complexing agent. Both groups of researchers obtained maximum resolution of ammonium and potassium cations using this complexant. Quang and Khaledi optimized the concentration of complexant α-HIBA using a simple univariate approach.[69] The researchers developed a migration model to predict the elution time of 14 metal cations

Table 4 IPD in CE separation of inorganic cations

Analytes	Sample	IPD reagent	Electrolyte system	Detection λ (nm)	Ref.
Lithium, sodium, potassium, calcium, magnesium, barium	Standard mixture; apple vinegar	Imidazole	5 mM Imidazole, pH 4.5	214	25
Potassium, barium, calcium, sodium, magnesium, lithium	Standard mixture	Imidazole	5 mM imidazole and (a) 2.1 mM acetic acid, pH 6 (b) 4.5 mM glycolic acid, pH 4 (c) 5 mM lactic acid, pH 4 (d) 6.4 mM α-HIBA, pH 4 (e) 1.9 mM oxalic acid, pH 4 (f) 0.1 mM citric acid, pH 4 (g) 3.6 mM malic acid, pH 4	214	66
Ammonium, potassium, sodium, lithium, magnesium, strontium, barium, manganese, nickel, zinc, copper	Standard mixture; Chinese tea infusion	Imidazole	5 mM Imidazole, 6.5 mM α-HIBA–20% methanol, 0.53 mM 18-crown-6	214	67
Ammonium, potassium, calcium, sodium, magnesium, lithium	Standard mixture	Imidazole	10 mM Imidazole, 2.5 mM 18-crown-6, pH 4.5	214	68
Potassium, barium, strontium, calcium, sodium, magnesium, manganese, cadmium, iron, cobalt, lithium, nickel, zinc, copper	Standard mixture; tapwater	Imidazole; benzylamine	6 mM Imidazole (pH 3.95) or 6 mM benzylamine (pH 4), 12 mM α-HIBA	214 210	69
Potassium, calcium, sodium, magnesium, copper	Standard mixture; fruit juice; acid etching bath	4-Methylbenzylamine (MBA)	5 mM MBA, 6.5 mM α-HIBA, pH 4.4	214	70
Potassium, barium, strontium, calcium, sodium, magnesium, manganese, cadmium, iron, cobalt, lead, nickel, lithium, zinc, copper	Standard mixture; cough syrup; fermentation bath	MBA	5 mM MBA, 6.5 mM α-HIBA, pH 4.4	214	71
Rubidium, potassium, calcium, sodium, magnesium, lithium, lanthanum, cerium, praseodymium, samarium, neodymium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium	Standard mixture	MBA	5 mM MBA, 4.0 mM α-HIBA, pH 4.4	214	71

Table 4 (*continued*)

Analytes	Sample	IPD reagent	Electrolyte system	Detection λ (nm)	Ref.

Ammonium, barium, potassium, sodium, calcium, magnesium, lithium	Standard mixture; drinking water	(a) $CuSO_4$ (b) Dimethyldiphenyl-phosphonium ion (DDP)	(a) 4 mM $CuSO_4$, 4 mM 18-crown-6, pH 3 (b) 5 mM DDP, 4 mM 18-crown-6, 5 mM morpholinoethanesulfonic acid, pH 6	215	80 81
Potassium, barium, lithium, calcium, sodium, magnesium, zinc, cadmium, chromium	Standard mixture	2-Aminopyridine (2-AP)	15 mM 2-AP, acetate buffer, pH 5	214	82
Potassium, calcium, ammonium, magnesium, manganese	Ultrex-grade hydrogen peroxide	MBA UV-Cat(II)	(a) 5 mM MBA, 6.5 mM α-HIBA, pH 4.4 (b) 1.2 mM UV-Cat(II), 6.5 mM α-HIBA, 3 mM tropolone, pH 4.4	185	83

as a function of pH and α-HIBA concentrations. The computer simulation predicted the optimal conditions to be 12 mM α-HIBA and pH 3.5. Again, 6 mM imidazole was used at the optimal pH and complexant concentration that provided a fast separation of metal cations in <4 min.

Monofunctional aromatic bases such as 4-methylbenzylamine,[70,72] *N*,*N*-dimethylbenzylamine,[73] benzylamine, and pyridine[73–75] have been shown to provide good CZE separation of mono-, di-, and trivalent cations. Weston et al.[70,71] showed that the simultaneous CZE separation of alkali, alkaline earth, and transition metals, as well as lanthanides, is possible using 5 mM MBA electrolyte and 6.5 mM α-HIBA at pH 4.4. Using this IPD electrolyte, they reported ca. 100 μg L^{-1} detection limits

Figure 13 Separation of alkali and alkaline earth metal ions under optimum conditions: 5 mM imidazole, pH 4.5; 25 kV, 9 μA; sample concentration 1 ppm. (Reproduced with permission from Beck and Engelhardt.[25])

Figure 14 Separation of 27 inorganic cations with 4-methylbenzylamine/lactate electrolyte. Conditions: 8 mM 4-methylbenzylamine/15 mM lactic acid/5% methanol, pH 4.25; 75 μm i.d. × 60 cm capillary; 30-s injection; +30 kV; UV detection at 214 nm. Peaks: (1) potassium; (2) barium; (3) strontium; (4) sodium; (5) calcium; (6) magnesium; (7) manganese(II); (8) cadmium(II); (9) lithium; (10) cobalt(II); (11) lead(II); (12) nickel(II); (13) zinc(II); (14) lanthanum(III); (15) cerium(III); (16) praseodymium(III); (17) neodymium(III); (18) samarium(III); (19) gadolinium(III); (20) copper(II); (21) terbium(III); (22) dysprosium(III); (23) holmium(III); (24) erbium(III); (25) thulium(III); (26) ytterbium(III); (27) lutetium(III). Sample: 1–5 μg mL^{-1} of each cation. (Reproduced with permission from Shi and Fritz.[72])

for 28 metals. The peak capacity for cation separations in CZE is not as high as for anions. However, indications of improved peak capacity have been reported by Shi and Fritz.[72] Using 8 mM MBA, 15 mM lactic acid, and 5% methanol at a pH of 4.25, resolution of 27 metal cations

in a single run was achieved in only 6 min (Figure 14). In a separate paper Shi and Fritz were able to resolve potassium and ammonium ions when crown ether was added to the same IPD reagent.[76] Further addition of crown ether caused Sr^{2+} to move ahead of Ba^{2+} and allowed the resolution of these ions. The authors also suggested the use of 8% methanol with low applied voltage and low injection size as a possible solution to the problem of determining a trace amount of metal ions (e.g. 1 ppm Ca^{2+}, Mg^{2+}, Sr^{2+}, or Ba^{2+}) in the presence of a very high concentration of another metal ion (e.g. 1000 ppm of Na^{+}). On the other hand, Yang et al.[77] have advocated the use of an imidazole–sulfuric acid buffer system rather than MBA as a means of improving the peak shapes of sodium when injected at high concentration. Chen and Cassidy[73] optimized the CZE separation of metal cations in terms of the nature of the IPD reagent, the concentration of the complexant, the pH, and the surfactant type and concentration. Optimal conditions were 6 mM *N*,*N*-dimethylbenzylamine, 4.2 mM HIBA, and 0.2 mM Triton X-100 at pH 5.0 (adjusted with acetic acid). Under these conditions CZE separations of 26 metal cations was attained in <11 min. The detection limits were in the range 0.6–1 $\mu g\,mL^{-1}$ for lanthanide, transition and alkaline earth metal ions, and in the range 0.1–0.8 $\mu g\,mL^{-1}$ for alkali metal ions.

Several other IPD reagents have been described for CZE separation of inorganic cations. These include ephedrine,[74,78] benzimidazole,[79] copper(II),[80] diphenylphosphonium hydroxide,[81] 2-AP,[82] and guanidine · HCl.[83] In general, they have all shown good CZE separation of metal cations but not exceptionally high peak capacity. Of the various cationic IPD electrolytes described in this section, imidazole and MBA seem to provide the best overall performance in terms of selectivity, resolution, and peak capacity of inorganic cations. However, more work is still needed to improve the peak capacity for cation separations up to the level achieved for IPD of anions.

3.3 Indirect Photometric Detection of Short-chain Organic Acids and Amines

IPD is normally required for the analysis of most short-chain polar anions of organic acids (e.g. oxalate, malonate, formate, acetate, and propionate). This is because many of these organic acids do not fluoresce and have negligible absorbance at useful wavelengths in the

Table 5 IPD in CE separation of short-chain organic acids and amines

Analytes	Sample	IPD reagent	Electrolyte system	Detection λ (nm)	Ref.
Short-chain organic acids					
Formate, carbonate, methanesulfonate, acetate, chloroacetate, dichloroacetate, propionate, succinate, butyrate, benzoate, fumarate, glutarate, adipate, pimelate, suberate, azelate, sebacate, formate, oxalate	Standard mixture; air extracts (solid and liquid)	2,6-NDC	2 mM NDC, 5 mM NaOH, 0.5 mM TTAB, pH 11.0	280	84
Methanesulfonate, ethanesulfonate, propanesulfonate, butanesulfonate, pentanesulfonate, hexanesulfonate	Standard mixture	NDC	2 mM NDC, 5 mM NaOH, 0.5 mM TTAB, pH 8.0	280	84
Mesoxalic acid, pyruvic acid, glyoxylic acid, citraconic acid, mesaconic acid, citric acid, glutaconic acid, itaconic acid, 2-hydroxybutyric acid, acrylic acid, glutaric acid, methacrylic acid, acetic acid, crotonic acid, butyric acid	Standard mixture	Phthalate	5 mM Phthalate, 0.001% (w/v) polybrene, pH 3.85	185	88
Acetate, propionate, butyrate	Standard mixture	NDC	1 mM NDC, 3 mM β-cyclodextrin, pH 9.0	240	85

Table 5 (*continued*)

Analytes	Sample	IPD reagent	Electrolyte system	Detection λ (nm)	Ref.
Oxalate, citrate, malonate, tartrate, methylmalonate, methylglutarate, lactate, ethylmalonate, adipate, methylsuccinate, pyruvate, succinate, glutarate	Standard mixture; urine	Phthalate	(a) 5 mM Carbonate, 1.5 mM phthalate, pH 7.0 (polyacrylamide-coated capillary) (b) 5 mM Carbonate, 1.5 mM phthalate, pH 9.0, 0.15 mM MTAB (c) 5 mM Carbonate, 1.5 mM phthalate, pH 8.9 (uncoated capillary)	230	86
Oxalate, formate, acetate, propionate, butyrate, benzoate, methanesulfonate	Standard mixture	(a) Chromate	(a) 5 mM Chromate, 0.5 mM TTAB, pH 8.0	(a) 254	87
		(b) PMA	(b) 2.25 mM PMA, 0.75 mM NaOH, 1.6 mM triethylamine, pH 7.7	(b) 254	
		(c) Phthalate	(c) 5 mM Phthalate or NDC, 0.5 mM TTAB, 1.0 mM H_3BO_3, pH 6	(c) 254	
		(d) NDC	(d) 2 mM NDC, 0.5 mM TTAB, 5 mM NaOH, pH 11	(d) 280	
Formate, malonate, citrate, succinate, pyruvate, acetate, lactate, pyroglutamate	Standard mixture; beverages	2,6-Pyridinedicarboxylic acid (PDA)	5 mM PDA, 0.5 mM CTAB, pH 5.6	200	89
Propionic acid, acetic acid, ascorbic acid, lactic acid, formic acid, citric acid, malic acid, tartaric acid	Standard mixture	8-Hydroxyquinoline-5-sulfonic acid (8-HQSA); 1,2,4,5-benzenetetracarboxylic acid (BTA)	5 mM HQSA or 3 mM BTA, pH 3	290	90
Oxalate, malonate, formate, succinate, maleate, tartrate, fumarate, malate, citrate	Standard mixture	NDS; NTS	4 mM NDS or NTS, 100 mM H_3BO_3, 5 mM $Na_2B_4O_7$, 2 mM DETA, pH 8	288, 284	35
Short-chain organic amines					
Diethylamine, triethylamine, diethanolamine, triethanolamine	Standard mixture	Imidazole	5 mM Imidazole, pH 4.25	214	25
Putrescine, L-histidine, spermidine, spermine, L-lysine, L-arginine	Standard mixture; tumor cells	Quinine sulfate	8 mM Quinine sulfate, 20% ethanol, pH 5.9	236	92
Ammonia, methylamine, 1,3-diaminopropane, putrescine, histamine, cadaverine, agmatine, ethylamine, ethanolamine, spermidine, propylamine, morpholine, isopropylamine, diethylamine, butylamine, spermine, isobutylamine, 1-methylbutylamine, hexylamine, tyramine, phenethylamine	Standard mixture; synthetic samples	$CuSO_4$	4 mM $CuSO_4$, 4 mM formic acid, 4 mM 18-crown-6	210	93

CTAB, cetyltrimethylammonium bromide; MTAB, myristoyltrimethylammonium bromide.

UV region. Various IPD electrolytes have been used in the analysis of organic acids. Again, the choice of the IPD reagent is governed by the need to obtain symmetrical peak shapes by closely matching their charge and electrophoretic mobility with those of the organic acids. Wu et al. evaluated chromate, pyromellitate, trimellitate, phthalate, terphthalate, and benzoate as IPD reagents for the determination of 10 organic acids.[61] Trimellitate was found to be the most suitable reagent because it provided the closest mobility match to the analyte with the highest molar absorptivity. In addition, various IPD reagents such as naphthalenedicarboxylic acid (NDC),[48,84,85] trimellitate,[47,60–62] phthalate,[20,39,86–88] NDS and NTS[35] all have suitable molar absorptivity and mobility matches that enable them to be of use for IPD of organic acids.

IPD has proved to be reliable for the quantitation of organic acids in real samples (e.g. urine,[86] beverages,[89] Bayer liquor[90]). However, the IPD method requires appropriate capillary conditioning procedures. For example, Soga and Ross found that when phthalate or trimellitate was employed as IPD reagent for the determination of organic acids, citrate and oxalate were not observed at concentrations below 50 mg L^{-1}.[89] Additionally, the S/N of malate deteriorated. The authors concluded that the decrease in S/N was due to adsorption of these organic acids onto the capillary wall. A procedure for rinsing the capillary with phosphoric acid before each run was proposed. However, a large phosphate peak appeared, which masked the analyte peaks. The use of a pyridinium chloride electrolyte was proposed as an alternative. This IPD electrolyte has the potential to complex with the metal impurities on the capillary wall, hence reducing the adsorption of the organic acids.

Table 5 lists the range of organic acids that have been analyzed employing CZE with IPD. Generally, the determinations of organic acids using the IPD method have been successful. Figure 15 shows an electropherogram obtained for the analysis of 18 organic acids in <7 min.[91] Although sensitivity in CZE is undoubtedly a major limitation, many IPD reagents (e.g. NDC, NDS) can be employed to lower the LOD.[84,85] The utility of CZE for the simultaneous measurement of short-chain organic acids and inorganic anions can be appreciated by considering the separation power and time as benefits of this technique. It should be noted that neither ion-exchange high-performance liquid chromatography (HPLC) nor ion-exclusion HPLC provides a complete separation of these compounds in IPD mode.

Even though there are a great number of samples that contain organic bases such as biogenic polyamines, food samples are the most common applications. Problems are often encountered with conductometric cation-exchange

Figure 15 Capillary electropherogram of an 18-component organic acid mixture: (1) oxalic acid, (2) formic acid, (3) fumaric acid, (4) pyruvic acid, (5) maleic acid, (6) L-malic acid, (7) citric acid, (8) lactic acid, (9) succinic acid, (10) D,L-aspartic acid, (11) D-glucoronic acid, (12) D-gluconic acid, (13) acetic acid, (14) L-ascorbic acid, (15) shikimic acid, (16) gallic acid, (17) propionic acid, and (18) *n*-butyric acid. HPLC for the analysis of short-chain polyamines because these polyprotonated species are highly charged in typical acidic eluents. Unless the eluent pH is high, the elution of polyamines using cation-exchange chromatography is problematic. For these reasons, CZE with IPD is attractive because it affords a simple means of facilitating both separation and detection. The potential of CZE with IPD for the determination of biogenic amines has been recognized by several authors. One of the early reports in the IPD of amines is by Beck and Engelhardt.[25] Simultaneous separation of metal ions, amines, and amino alcohols was obtained using 5 mM imidazole as the IPD electrolyte at a pH of 4.5. A complete CZE separation was achieved in ca. 4 min, with a C_{LOD} of around 0.4 ppm. Some polyamines (e.g. putrescine, spermine, and spermidine) along with inorganic cations and basic amino acids in tumor cells were determined simultaneously in <10 min by Ma et al.[92] The system employed quinine sulfate as IPD reagent at a pH of 5.9. Mass detection limits attained by this method were in the femtomole range with a linear detection response of two orders of magnitude. Extensive optimizations by Arce et al.[93] have shown that cupric sulfate is an ideal IPD electrolyte for the detection of biogenic amines. A rapid separation of 21 amines using this optimized electrolyte system is shown in Figure 16. A typical detection limit attained by this method for biogenic amines was 0.05 ppm. Although the linear concentration range (0.05–10 ppm) was rather narrow, the recoveries (90–110%) obtained for the representative amines were reasonable.

Figure 16 Electropherogram of a standard mixture of amines: (1) ammonia; (2) methylamine; (3) 1,3-diaminopropane; (4) putrescine; (5) histamine; (6) cadaverine; (7) agmatine; (8) ethylamine; (9) ethanolamine; (10) spermidine; (11) propylamine and morpholine; (12) isopropylamine; (13) diethylamine; (14) butylamine; (15) spermine and isobutylamine; (16) amylamine and isoamylamine; (17) 1-methylbutylamine; (18) hexylamine; (19) phenylethylamine; (20) heptylamine; (21) tyramine. The electrolyte comprised 4 mM cupric sulfate, 4 mM formic acid and 4 mM 18-crown-6 at pH 3.0. The separation was performed at 10 kV. 3.4 Indirect Photometric Detection of Long-chain Fatty Acids

Long-chain free fatty acids (FFAs) are an important class of naturally occurring compounds that can be found in living cells. Because these compounds contain an acidic hydrogen, they predominantly exist as anions in basic solution. Considering the differences in mass-to-charge ratios, both saturated and unsaturated FFAs can be separated by CZE. However, saturated FFAs exhibit only a weak absorption band in the region of 200 nm. Therefore, CZE with direct UV detection is problematic and leads to limited sensitivity. Currently, CZE with IPD is of considerable interest for the determination of long-chain saturated FFAs (Table 6).[45,94–98]

Probably the first attempt to separate long-chain FFAs in CZE with IPD was reported in 1994 by Gutnikow et al.[94] Both normal and reversed electroosmotic flow in CZE was developed using TNBSA as the IPD reagent. Although, a rapid separation in <7 min of FFAs up to C_{10} was achieved in reversed electroosmotic flow mode using 30% acetone, peak capacity was much higher in the normal mode. For example, in the normal mode, analysis of C_3-C_{18} organic acids was feasible in <20 min using 60% acetonitrile. Despite the use of low-mobility TNBSA as the IPD reagent, the electropherogram showed asymmetric peaks for $C_{14}-C_{18}$ FFAs. Buchberger et al.[95] resolved both short- and long-chain FFAs in a reversed CZE mode with reversed polarity. The solubility parameters and adsorption of FFAs on capillary walls were overcome with the use of 70% ethyleneglycol monomethyl ether and trimethylammonium propanesulfonate in the IPD buffer. The FFAs in butter were profiled; however, one of the limitations of this method was its inability to resolve isomers of FFAs. Nevertheless, the simplicity of the sample preparation could be beneficial for routine analysis.

Roldan-Assad and Gariel developed a CZE method for the determination of C_2-C_{14} linear FFAs.[45] Because long-chain FFAs ($\geq C_{14}$) have limited water solubility and their tendency to form micelles decreases the separation selectivity between successive homologs, IPD electrolytes containing cyclodextrins and 60% methanol were used to enhance both solubility and selectivity. However, this occurred at the expense of a slightly longer analysis time (>16 min). The C_{LOD} values of FFAs were approximately 0.2 ppm (1×10^{-6} mol L^{-1}) and the detection linearity was extended over three orders of magnitude (10^{-6}–10^{-3} mol L^{-1}). Collet and Gariel[96] later studied the effect of cyclodextrin type and concentration for the separation and indirect detection of saturated and unsaturated FFAs ranging between C_{14} and C_{18}. The authors concluded that the CZE method developed using cyclodextrin was not suitable for the separation and IPD of very-long-chain ($C_{19}-C_{31}$) FFAs.

Drange et al.[97] first used nonaqueous electrolyte for CZE separation of very-long-chain FFAs. The authors showed that the separation of $C_{14}-C_{26}$ acids could be accomplished conveniently in 15 min using ANTs in *N*-methylformamide and dioxane. Recently, Haddadian et al. investigated the CZE separation of long-chain saturated $C_{12}-C_{31}$ FFAs differing by only one carbon atom.[98] Figure 17 shows an impressive separation of $C_{12}-C_{31}$ FFAs under the optimum conditions using AMP as IPD reagent. Because AMP was found to be soluble in aqueous and partially aqueous, as well as nonaqueous media, it appears to be an excellent IPD electrolyte for the separation and IPD of complicated mixtures of both saturated and unsaturated FFA isomers (Figure 18).

3.5 Indirect Photometric Detection of Phosphates and Phosphonates

CZE with IPD has recently emerged as a valid alternative to the more traditional postcolumn IC method for the determination of both phosphates and phosphonates (Table 7).[24,99–101] Advantages of CZE over IC for these

compounds are large peak capacity, short analysis time, better efficiency, and minimal sample and reagent consumption. Despite the fact that Jones and Jandik demonstrated chromate to be the best IPD electrolyte for the separation of 30 inorganic anions and short-chain organic acids in ca. 3.0 min, the utility of chromate for the separation of relatively high-molecular-weight and less-mobile phosphates and phosphonates is poor. For example, peak tailing and poor migration time and area reproducibility of orthophosphate were observed by a number of researchers using a chromate electrolyte.[102–105] Theoretical considerations suggest that reagents that can be useful for indirect detection of phosphate and phosponate derivatives should have medium to low mobility, a relatively high ε, and a favorable DR.

Linear polymers of phosphoric acid, all of which contain phosphorus–oxygen linkages, are termed linear P_n. The first report on CZE/IPD applied to the separation of P_1-P_3 phosphates using a phthalate electrolyte at a pH of 4.0 was described by Stover et al.[99] However, the system was not fully optimized and the method was reported to have marginal baseline stability and

reproducibility. When the calibration plots of normalized peak area vs. concentration were drawn for P_1, P_2 and P_3 phosphates, approximately the same slopes but different intercepts were observed. For example, P_2 and P_3 phosphates provided nearly equal slope values but large negative intercepts. The authors concluded that the reason for the low detection sensitivity of P_2 and P_3 phosphates might include interaction with the surfactant (e.g. dodecyltrimethylammonium bromide used as a modifier for reverse electroosmotic flow) and/or on-line hydrolysis. In an attempt to improve the reproducibility, Shamsi and Danielson first evaluated the use of ribonucleotides, namely AMP, CMP, GMP, and UMP, as IPD electrolytes for the simultaneous separation of 12 P_n and RP_n in <30 min.[24] These reagents contain a phosphate group in their structure, thus preventing any irreversible binding of P_n and RP_n with the silanol groups. Even though all of the ribonucleotides were able to separate a mixture of P_n and RP_n with reasonable selectivity, AMP was found to be the best electrolyte because of the its high ε, large DR and favorable TR required for sensitive IPD. The quality of separation of some P_n (particularly P_3 and P_4 phosphates) was dramatically improved by incorporating Mg^{2+} in the running buffer with positive polarity. As a result, the reproducibility of migration times is 0.5–1.0% relative standard deviation (RSD). One practical application reported was the determination of phosphates and phosphonates in soap and various brands of toothpaste. Later Wang and Li[100,105] reported the use of ATP at pH 3.5 for the CZE separation and IPD of cyclic P_3 phosphate, monofluorophosphate and P_1-P_3 phosphates. Although the value of DR for ATP was 2.8×10^3, which is much greater than that obtained by Shamsi et al.[24] using AMP (DR = 612), the detection limits for P_n were not improved. This implies that the greater DR obtained for ATP was compensated by a loss in TR.

The CZE separation of P_n with chain length ≥ 4 is more challenging because of their similar electrophoretic mobility. Again, Stover first explored the buffer containing PMA with hexamethonium hydroxide for high-efficiency separation and IPD of P_n.[106] Glassy sodium P_n with average chain lengths of 5–44 were analyzed in less than 20 min. Stover thought that the cationic electroosmotic flow modifier hexamethonium would ion-pair with the anionic P_n leading to improved CZE separation. After this success in the CZE mode, Wang and Li recently reported the separation of higher-chain-length P_n using capillary gel electrophoresis (CGE).[107] Presumably, the sieving effect of the gel provided good resolution of P_n. Wang and Li used the same PMA electrolyte as Stover used,[106] but without the use of hexamethonium hydroxide. The migration order of linear P_n was found to be based on charge-to-size ratios. For example, migration time first increased from P_2 to P_4 phosphate, but P_1 phosphate eluted later, followed by all linear P_n. The authors reported that quantitative analysis of P_n was difficult due to the bias generated by the electrokinetic injection. Currently, systematic approaches to the design of a novel buffer system and IPD reagents that offer enhanced selectivity and sensitivity for long-chain P_n are still being developed. As yet, they are not at the point where buffer recipes can be employed conveniently for routine separations of these long-chain P_n in CZE or CGE mode. However, there is no doubt that CE methods for P_n will substitute for IC in specific applications.

IPD of inositol phosphates after their separation by CZE was studied by Henshall et al.[39] at low pH using a dichromate and phthalate electrolyte. Although the use of chromate provided separation of all four inositol (mono-, bis-, tris-, and hexakis-) phosphates in less than 10 min, the separation window was rather narrow (0.7 min) and therefore shifts in the migration time resulted in peak misidentification. On the other hand, phthalate when buffered at pH 5.9 provided acceptable results with excellent sensitivity for the inositol mono- and bis-phosphate, but this electrolyte does not seem to be useful for the separation of all four inositol phosphates in a single run. The CZE/IPD methodology for the determination of six inositol phosphates in fermentation broth was also investigated by Buscher et al.[108] Using 1-naphthol-3,6-disulfonic acid (NDSA) as the IPD reagent, the authors reported the baseline resolution of inositol mono-, bis-, tris-, and tetrakisphosphates, whereas inositol pentakis- and hexakisphosphates remain unresolved.

Figure 19 Effect of pH on the separation of a standard mixture of 10 mono- and diesters of phosphates: (a) AMP at pH 7.2; (b) AMP at pH 10.5. All electrolytes contained 100 mM H_3BO_3. Peak identification: 100 mg mL^{-1} each of (1) diethylhexylphosphate; (2) dibutylphosphate; (3) diisopropylphosphate; (4) diethylphosphate; (5) monoethylhexylphosphate; (6) monobutylphosphate; (7) monoisopropylphosphate; (8) monoethylphosphate; (9) monomethylphosphate; (10) dimethylphosphate. Vacuum injection for 2 s; +30 kV applied for separation; current is 8 μA and 70 μA at pH 7.2 and 10.5, respectively; IPD at 259 nm. (Reproduced with permission from Shamsi and Danielson.[109])

Inositol trisphosphate was the only compound that provided a closer mobility match to NDSA, resulting in symmetrical peak shape. Hence, this approach was extended further by the same authors for the analysis of inositol trisphosphate in plasma.[41]

Phosphorus-containing surfactants, namely mono- and diesters of aliphatic organophosphates, are used in a wide variety of applications. The determination of these compounds is of relevance not only in the detergent industry, owing to their surface-active property, but also in medicinal research, as well as the nuclear and fuel processing industry. Recently, Shamsi et al.[109] developed a CZE/IPD method for analysis of alkyl phosphates. An example electropherogram showed that the separation of 10 C_1-C_6 mono- and diesters of phosphate is possible in ca. 11 min using AMP electrolyte at pH 7.2 (Figure 19a). Although the resolutions of some phosphate esters were improved at a higher pH value of 10.5, the S/N decreased significantly under such conditions (Figure 19b). Hence, a pH of 7.2 was recommended for the analysis of these aliphatic organophosphates.

Alkylphosphonic acids have considerable agricultural and biological importance due to their biocidal potency and their presence at trace levels in various antibacterial (fosfomycin) or antiviral (foscarnet) formulations. Pianetti et al. have utilized PPA at 200 nm for the IPD of C_1-C_4 phosphonates in less than 10 min.[110] The authors reported that an increase in borate concentration resulted in a better S/N. In contrast, S/N decreased with increasing concentration of PPA. The calibration plots based on peak height for C_1-C_4 phosphonates showed a linear range of 5–50 μg mL^{-1} with an RSD of less than 3.8%. Moreover, the mass LOD of alkylphosphonic acids was

Figure 20 Separation of alkylphosphonic acids. Experimental conditions: buffer is 200 mM borate and 10 mM PPA; 75 μm (i.d.) × 56 cm fused-silica capillary; peaks detected by indirect UV detection at 210 nm; injection for 6 s at 50 mbar; temperature = 40 °C; 0.35 mM didodecyldimethylammonium hydroxide and 0.03 wt.% Triton X-100, pH 4.0; voltage = 30 kV (negative polarity). Anions: (1) *O*-(2-ethylhexyl)methylphosphonic acid; (2) methylphosphonate; (3) ethylmethylphosphonate; (4) isopropylmethylphosphonate; (5) isobutylmethylphosphonate; (6) *O*-isopropylethylphosphonic acid; (7) cyclohexylmethylphosphonate; (8) pinacolylmethylphosphonate. ca. 0.21 pmol. Another application of phosphonate compounds is glyphosate, with its major metabolite AMPA. Shamsi et al.[24] also developed a normal-polarity CE method using AMP electrolyte for quantitation of these two analytes in a commercial herbicide solution. Likewise, Cikalo et al.[111] also reported the analysis of glyphosate and AMPA using CZE/IPD. However, these employed a reverse-polarity CE with phthalate as the IPD reagent. Although the use of electrokinetic injection provided improved detection limits, the application of the method to wheat samples was unsuccessful. This is because of the high conductivity of the extracted sample, which prevented injection in the electrokinetic mode. Very recently, Nassar et al.[101,112] in a series of two publications used PPA as the IPD electrolyte for the separation and indirect detection of short-chain alkylphosphonates (also known as chemical warfare agent degradation products). The phosphonates studied included methylphosphonic acid, monoisopropylphosphonic acid, and the monoalkyl esters of methylphosphonic acid. Using a mixed surfactant system (0.35 mM didodecyltrimethyl ammonium hydroxide, 0.03 wt.% Triton X-100) to reverse the electroosmotic flow, and PPA as the IPD electrolyte, complete separation of phosphonates was accomplished in less than

3 min (Figure 20).[101] The authors found this electrolyte system to be stable for at least three months. The detection limit reported was about 100 μg L^{-1}. Moreover, the method was applied to the aqueous leachates of soil, wipes of surfaces, and vegetation samples known to have been exposed to nerve agents. Nassar et al.[112] in the same laboratory expanded this work with quantitative analysis of chemical warfare degradation products in reaction masses. They found that the CZE/IPD methodology can provide a limit of quantitation of 500 μg L^{-1} and an LOD of 100 μg L^{-1} for both isopropylmethylphosphonic acid and pinacolylmethylphosphonic acid, with a linear response over the range 0.5–100 μg L^{-1}.

3.6 Indirect Photometric Detection of Aliphatic Anionic and Cationic Surfactants

Aliphatic anionic and cationic surfactants are important additives that are widely used as cleaning agents, dispersants, emulsifiers, solubilizers, and stabilizers. Structurally, many of these compounds consist of an aliphatic hydrocarbon tail with a polar head group and nonchromophoric substituent. Recent reports on the separation of nonchromophoric anionic surfactants indicate that CE is a complementary technique to reversed-phase IC with respect to retention order.[35,113,114] In addition, minimal organic solvent consumption and inexpensive column replacement are practical benefits of CE besides its inherent good peak capacity.

In the analysis of anionic and cationic surfactants (Table 8), a medium- to low-mobility IPD co-ion must be chosen. For the determination of nonchromophoric anionic surfactants such as alkyl sulfates, alkane sulfonates, alkylether sulfates, and alkylsulfosuccinates, several IPD reagents have been explored. Numerous IPD electrolytes used for anionic surfactants include veronal, NMS,[7,35,113–115] salicylate,[116] dihydroxybenzoic acid,[117] PTS,[113,118] dinitrobenzoic acid,[119] AMP,[114] and octyl- and dodecylbenzene sulfonate.[115] In contrast, there are only a few reports on the CZE separation of non-UV-active cationic surfactants. The strong adsorption of these substances at the inner wall of a fused-silica capillary is clearly a matter of concern. However, recent reports have indicated that a large volume of organic solvents can help to overcome this problem.[120,121] By far the more prominent IPD reagents for cationic surfactants include benzyldimethyldodecylammonium,[120] benzylamine,[114] ephedrine,[113,114] benzyltrimethylammonium,[121] and tetrazolium violet.[114]

The separation of complex mixtures of alkyl sulfates and alkane sulfonates of identical chain length is a challenging problem in CZE because of their very similar electrophoretic mobilities. Figure 21 is a typical electropherogram obtained using the best anionic IPD reagent, such as NMS with 50% methanol, to enable the baseline separation of C_6–C_{18} SO_4^-/SO_3^- pairs in 30 min. A similar electropherogram but with lower sensitivity could be generated with PTS as the IPD reagent.

Figure 21 Separation of a standard mixture of anionic sulfonated and sulfated surfactants. Electrolyte consisted of 5 mM NMS with 100 mM H_3BO_3 (pH 6.0) and 50% methanol. Peak identification: 100 mg mL^{-1} each of (1) C_{18} SO_3^-, (2) C_{18} SO_4^-, (3) C_{14} SO_3^-, (4) C_{14} SO_4^-, (5) C_{12} SO_3^-, (6) C_{12} SO_4^-, (7) C_{10} SO_3^-, (8) C_{10} SO_4^-, (9) C_8 SO_3^-, (10) C_8 SO_4^-, (11) C_6 SO_3^-, and (12) C_6 SO_4^-. 3.7 Indirect Photometric Detection of Carbohydrates

The determination of carbohydrates (Table 9) provides a unique challenge to a separation chemist. This is because most carbohydrates do not possess strong chromophores in their structure and are therefore not accessible to direct detection in the UV. For these reasons, carbohydrates are generally derivatized with a suitable chromophore such as 2-AP[122] or *p*-aminobenzoic acid[123] for direct UV detection, or by indirect detection[23,123] using a suitable light-absorbing reagent. It is well known that carbohydrates are very weak acids; therefore very-high-pH eluents have been used for their separation via anion-exchange chromatography.[124,125] A number of researchers have also utilized high-pH (pH ~ 12) electrolytes for the CZE separation of carbohydrates in the IPD mode.

Vorndran et al.[23,51] have shown that sorbic acid is a very useful IPD reagent for several important reasons. First, sorbic acid has high molar absorptivity (ε = 27 800 at 256 nm). Second, it carries a single charge, which ensures a favorable TR value. Third, it does not interact with the

NAA, 1-naphthylacetic acid.

capillary surface or with the analyte. Fourth, it has an effective mobility that matches well with the mobilities of the ionized sugars. Vorndran et al.[23] found increased resolution of carbohydrates as the pH was increased, but a drastic drop in IPD sensitivity was observed as the pH increased past 12.2. They postulated that the decrease in IPD sensitivity is probably due to the displacement of nonabsorbing hydroxide ion, rather than sorbate ions, by the analytes. In addition they determined the best compromise pH for sensitive detection of carbohydrates to be 12.1. At this pH, C_{LOD} was about 0.5 mM. In a similar study, Vorndran et al.[51] investigated the effect of sorbate concentration on the IPD signal. The researchers reported that a lower concentration of sorbate adversely affects the TR value due to competition with hydroxide ion. On the other hand, at high sorbate concentrations S/N again deteriorates because less light is able to reach the photodiode. Likewise, Klockow et al.[126] used sorbate as an IPD reagent for the determination of carbohydrates in a variety of fruit juices. Again, the optimum CZE conditions were found with a buffer of pH 12.2–12.3.

Figure 22 Electropherogram of a mixture of eight selected monosaccharides (1 mM each) in 2 mM NAA, pH 12.2. CE conditions: capillary, 120 cm (113 cm to the detector) × 50 μm i.d.; voltage = +25 kV; temperature = 25 °C; indirect absorbance detection at 222 nm; hydrodynamic injection for 3 s. Peaks: 1 = sucrose; 2 = lactose; 3 = maltose; 4 = glucose; 5 = rhamnose; 6 = fructose; 7 = ribose; 8 = gluconic acid. (Reproduced with permission from Lee and Lin.[127])

Lee and Lin[127] have evaluated the potential of six IPD reagents for the determination of carbohydrates: NAA, 2-naphthalenesulfonic acid, 1,3-dihydroxynaphthalene, phenylacetic acid, *p*-cresol, and sorbic acid. They noted that NAA is the best IPD reagent for CZE separation of eight sugars (sucrose, lactose, maltose, glucose, rhamnose, ribose, gluconic acid) (Figure 22). In addition, NAA also provided a three- to sixfold increase in separation efficiency and about a fivefold improvement in the detection limit (0.1 mM) when compared with sorbate. Lu and Westerlund[128] reported the utility of tryptophan as another IPD electrolyte for the determination of carbohydrates, which provided at least a twofold improvement in detection limits over sorbate.

CZE/IPD of underivatized carbohydrate based on sorbate or riboflavin electrolytes has also been exploited by several researchers.[129,130] Xu et al.[129] have used narrow (25 μm) capillaries and low voltages at high pH to improve the C_{LOD} of underivatized sugars. After optimization of the CZE conditions, the pH range for the separation was extended to 13. The C_{LOD} of sugars at this high pH was of the order of 0.05–1.0 mM. The developed method was applied to the analysis of culture medium samples. Liu et al.[130] reported a three- to fivefold improvement in separation efficiency with a stable baseline using diethylamine as an electrolyte additive, when compared to sodium hydroxide, at a pH as high as 12.6. It was hypothesized that low-conductivity diethylamine forms ion-pairs with anionic carbohydrates, and also suppresses electroosmotic flow by masking the silanol group at the capillary surface. The authors also reported improved separation of di- and trisaccharides with a borate buffer at pH 9.5, in place of sodium hydroxide or diethylamine, keeping the type of IPD reagent (sorbate, riboflavin) constant for both variations.

CZE/IPD for the qualitative and quantitative analysis of low-molecular-weight glycosaminoglycans (heparins) was reported by Damm et al.[131] Although heparin fragments are also amenable to direct UV detection at 232 or 200 nm, the use of 5-sulfosalicylic acid or 1,2,4-tricarboxybenzoic acid in IPD mode provides an order of magnitude higher sensitivity than direct UV detection.

Cyclodextrins belong to another class of nonchromophoric carbohydrates that can be resolved by CZE provided that the IPD reagent binds selectively with the central hydrophobic core of the cyclodextrin molecules. Nardi et al.[132] separated α, β, γ-, and δ-cyclodextrins at a pH of 6.2 using 30 mM benzoic acid as the IPD reagent. The authors demonstrated that formation of an inclusion complex of benzoate with the cyclodextrins can be beneficial for quantitative analysis of the latter in drug formulation. Various charged and uncharged cyclodextrins have also been shown to be detected in the IPD mode after their CZE separation using a range of aromatic anions.[133–135] However, it is postulated that the absorbance difference caused by cyclodextrins is probably due to displacement of the IPD reagent in the sample zone rather than a specific absorption change caused by inclusion complex formation.

Very recently a mixture of six different phosphorylated sugars and other organophosphorus compounds of biochemical interest (e.g. glucose-6-phosphate, fructose-6-phosphate, fructose-1,6-biphosphate, dihydroxyacetone phosphate, glyceraldehyde-3-phosphate, 2-phosphoglycerate) found in the glycolytic pathway were resolved under CZE/IPD conditions by Schaeper et al.[136] They found optimum analysis with 5 mM AMP and 100 mM boric acid at a pH of 7.2. Although the authors reported successful separation of five monophosphorylated sugars using the same conditions as for the glycolytic pathway, the separation of bisphosphorylated sugars could not be achieved unless magnesium was added to the AMP buffer. On the other hand, when NDS was used as the IPD electrolyte, the separation of biphosphorylated sugars was

DMAB, 4-(*N*,*N*′-dimethylamino)benzoate.

possible without the addition of magnesium. With a 5-s vacuum injection into the capillary the authors reported a detection limit of 0.5–1 ppm (S/N = 3).

3.8 Indirect Photometric Detection of Amino Acids and Phospholipids

A number of publications have described the successful CZE separation of underivatized amino acids with IPD (Table 10).[137–141] Lee et al.[137] have evaluated nine IPD reagents for the analysis of a mixture of 20 common amino acids. The IPD reagents evaluated were sorbate, benzoate, phthalate, nicotinate, salicylate, *p*-aminosalicylate (PAS), *p*-aminobenzoate, DMAB, and 7-amino-4-hydroxy-2-naphthalenesulfonate (AHNS). These authors found that both type and concentration of the IPD reagents influence the separation behavior and detectability of amino acids. Two IPD reagents (PAS and DMAB) were recommended for the routine analysis of amino acids because they have effective mobilities that match closely the mobilities of most amino acids at high pH. For example, Figure 23 shows that the resolution of 17–19 amino acids can be achieved in 35 and 50 min, respectively, using PAS or DMAB, respectively, at pH 11 with normal polarity.[138] This was possible upon addition of 20 mM α-cyclodextrin to PAS or DMAB at pH 11.0 (Figure 23). In a systematic approach to separate amino acids, Chen et al.[139] used CZE with IPD for the analysis of amino acids in urine. Resolution was achieved by adjusting pH, buffer concentration, and

Figure 23 Electropherogram of 20 common amino acids in 10 mM PAS (a) and 10 mM DMAB (b) in the presence of 20 mM α-cyclodextrin (Sigma) at pH 11.0. Concentration of amino acids, 0.5 mM each. Peak identification: K = Lys, P = Pro, L = Leu, I = Ile (not resolved), W = Trp, F = Phe, M = Met, H = His, V = Val, Q = Gln, T = Thr, N = Asn, A = Ala, S = Ser, G = Gly, Y = Tyr, C = Cys, E = Glu, D = Asp. Arg is merged with the system peak (the first peak) and $*$ is an unknown peak. (Reproduced with permission from Lee and Lin.[138])

the type of IPD reagent (benzoate, salicylate). Similarly Hong et al.[140] have also optimized the separation of amino acids with IPD. They indicated that the choice of IPD reagent is critical for the efficiency of separation in CZE. Using the optimized conditions, baseline separation of 13 amino acids was reported. One recent report[142] demonstrated CZE separation of phosphoamino acids using AMP as the IPD reagent. Baseline resolution of three phosphoamino acids (phosphoserine, phosphothreonine, phosphotyrosine) without co-migration of two native amino acids (glutamic acid, aspartic acid) was accomplished in less than 20 min with detection limits in the micromolar range. An interesting application of the IPD method for the determination of phosphoserine in the protein phosvitin after acid hydrolysis was also described in this report.[142]

Currently, there are only a few reports on the CZE separation of anionic phospholipids (Table 10).[143–145] In the separation of these very hydrophobic anions, MEKC with direct UV detection is preferred. However, the C_{LOD} using direct detection is rather poor even at a wavelength of 200 nm. CZE/IPD was recently reported by Haddadian et al.[145] for the determination of $C_{12}-C_{18}$ phosphatidic acids, phosphatidylserine, phosphatidylinositol, phosphatidylglycerol, and cardiolipin, giving LOD values in the low-ppm range for these anionic phospholipids. The

authors demonstrated the versatility of AMP by utilizing it as the IPD reagent for the analysis of phospholipids in soybean and brain extracts.

4 SIMULTANEOUS SEPARATION AND INDIRECT DETECTION OF CATIONS AND ANIONS

The potential of CZE for the simultaneous separation of cations and anions with IPD holds particular promise for ion analysis for several important reasons. First, combined separation and detection is very convenient compared to individual separations because more information about sample cations and anions as well as the chemical processes can be obtained in a single run. Second, it is obvious that this approach is cost-effective with less work and a shorter analysis time. Although, at the present time, only few research groups worldwide are actively engaged in the development of these analytical methods, the method has the potential to broaden the scope of CZE applications.

Despite the merits discussed above, simultaneous separation and IPD of cations and anions is problematic in CZE because when the voltage is applied cations and anions tend to migrate inherently toward their respective electrodes. Because a detector is generally located on one side of the capillary, proper control of both migration direction and migration velocity is essential, so that the two classes of ions of opposite charges can move in the same direction. There are four major approaches that have been developed to cope with the aforementioned problem. The first approach utilizes Ce^{3+} and *p*-hydroxybenzoate counterions for IFD of some small inorganic cations and chloroanions respectively.[146] However, dual detectors (one at each end of the capillary) are required, making this approach difficult to adopt in a commercial CE system. The second approach, first reported and applied in IPD by Shamsi and Danielson[113] and later by Xiong and Li,[147,148] is based on the principle that if the velocity of electroosmotic flow is high enough, then both cations and anions can be determined in one run provided that they have a suitable mobility match with their respective indirect photometric co-ions. The third approach is described by Kuban et al.,[149] in which the detection window is placed approximately in the center of the capillary and the sample is injected from both ends of the capillary. Finally, the last approach reported recently[150] describes the metal cations being transformed into anionic chelates after their complexation with ethylenediaminetetraacetic acid. Hence, cations are separated together with anions under the co-electroosmotic flow conditions in CZE. Unfortunately, with this approach alkali metals and ammonium cations cannot be determined because they do not form stable complexes with ethylenediaminetetraacetic acid.

4.1 Selection of Suitable Cationic and Anionic Indirect Photometric Detection Reagents

In evaluating light-absorbing co-cations and co-anions for simultaneous separation and IPD of the nonchromophoric cations and anionic analytes, several factors should be considered:[113,147,148]

1. A two-component IPD solution must be chromophoric with high ε and DR.
2. The IPD reagent must provide a suitable mobility match, i.e. small ΔT value (ΔT = migration time of the IPD reagent minus the migration time of analyte ion).
3. IPD reagents should preferably be strong bases or acids to ensure that high fractions of both are ionized. For example, cationic IPD reagents should have a high pK_a value so that they can be displaced effectively by the nonchromophoric cationic analytes even at higher pH. In addition, anionic IPD reagents should be strong acids so that they could not only adjust the solution pH but also provide charge displacement with good sensitivity at low pH.
4. Contributions from the UV-absorbing counterions must be minimized. For this reason, mixing of free aromatic bases and acids (instead of salts) to generate a two-component IPD reagent is important. This procedure minimizes the dilution of UV-absorbing components by nonabsorbing extraneous spectator ions. Thus, a pH range of 6–7 appears to be favorable because this range minimizes the contribution of H^+ and OH^- ions (generated from the buffer), which in turn improves the detectability.
5. The light-absorbing reagents should not contain spectator ions that need to be detected in the sample. For example, the bromide salt of cationic IPD reagents will exhibit a negative system peak where bromide normally migrates in the electrolyte. This negative peak not only decreases the sensitivity for bromide but may also cause difficulties with integration of analytes migrating closer to bromide.[36]
6. The absorbance match of the IPD reagents should be as close as possible (i.e. ΔA should be minimum) so that neither the cation nor the anion is masking the absorbance of the other ion.
7. The total background absorbance should be additive and be within the linear range of the UV absorbance detector.

Figure 24 Comparison of benzylamine–PTS (BA-PTS) (a) and benzylamine–NMS (BA-NMS) (b) for the simultaneous separation of a standard mixture of cationic and anionic surfactants. Electrolyte consisted of 5 mM BA-PTS or BA-NMS with 100 mM H_3BO_3 (pH 6.0) and 50% methanol. Peak identification: 50 mg L^{-1} of (1) triethylamine; 25 mg L^{-1} each of (2) chloroethyltrimethylamine, (3) tetrabutylamine, (4) tetrahexylamine, and (5) didodecyldimethylamine; 50 mg L^{-1} each of (6) C_{18} SO_3^-, (7) C_{16} SO_3^-, (8) C_{14} SO_3^-, (9) C_{12} SO_3^-, (10) C_{10} SO_3^-, (11) C_8 SO_3^-, (12) C_7 SO_3^-, (13) C_6 SO_3^-, (14) C_5 SO_3^-, and (15) C_{18} SO_3^-. * is the water peak. Vacuum injection for 3 s; +30 kV applied for separation; current = 4–5 μA; IPD at 208 nm with BA-PTS and at 200 nm with BA-NMS. (Reproduced with permission from Shamsi and Danielson.[113] Copyright 1995 American Chemical Society.)

Some of the above-mentioned criteria were first evaluated by Shamsi and Danielson.[113] Benzylamine or pyridine bases were mixed with NMS or PTS to generate four different combinations of two-component IPD reagents. For the selection of a suitable wavelength for both IPD reagents (point 4), the background absorbance of 5 mM each of benzylamine, pyridine, PTS, or NMS was measured from the readout of the CE detector by flushing the capillary with light-absorbing solutions. The cation – anion background absorbance (ΔA) values for two combinations of electrolytes (benzylamine–PTS and benzylamine–NMS) were determined as a function of wavelength in 1–2 nm increments over the range 200–220 nm. The authors found the ΔA values to be +3 mAU and −61 mAU using benzylamine–PTS and benzylamine–NMS electrolytes at its minimum interference wavelength of 200 nm. Using this approach the authors compared the electropherogram obtained for the simultaneous separation and IPD of a 15-component mixture of cationic and anionic surfactants. As shown, the benzylamine–NMS electrolyte improved the detection of anionic surfactants because of the negative ΔA value (Figure 24b), but benzylamine–PTS detected cationic surfactants better, as predicted by the positive ΔA value (Figure 24a).

4.2 Selection of a Suitable pH

As discussed earlier (point 4, section 4.1) simultaneous separation and indirect detection should be optimized by a judicious selection of electrolyte pH. This is because not only the detection sensitivity but also the mobility of cationic and anionic IPD reagents and solute ions, and the magnitude of the electroosmotic flow, are affected by a change in the pH of the IPD solution. Xiang and Li verified experimentally the effect of pH using a seven-component model mixture of inorganic cations and anions.[148] A series of electropherograms obtained using pH values of 4.52, 5.00, 5.42, 6.00, 6.52, 7.04, 7.53, and 8.03 are shown in Figure 25 on the same sensitivity scale. As the pH value is increased, the peak efficiency of anionic solutes is increased. It is apparent that only two out of five anionic solutes could be detected when the pH was less than 6.00 (Figure 25, spectra a–c). On the other hand, resolutions for both cations and anions were not feasible at pH > 7.50 (Figure 25, spectra g and h). Thus, as predicted earlier by Shamsi et al., and verified experimentally by Xiang et al., the use of pH 6–7 (Figure 25, spectra e and f) seems to be the best pH range for the joint separation and IPD of anions and cations.

4.3 Effect of Indirect Photometric Detection Binary Electrolyte Concentration

Xiong et al.[148] studied the effect of a two-component IPD electrolyte (imidazole and sulfosalicylic acid) concentration at constant pH on the selectivity of cation and anion separation. They determined that by increasing the total IPD electrolyte concentration, selectivity for the separation of cations and anions (within their individual groups) increased at pH 6.52 and 7.04. However, it was also clear that the enhancement in cation selectivity is not as significant as that for anion separation. Moreover, it was found that when the total IPD electrolyte

Figure 25 Electropherograms of the model sample mixture in the binary background electrolyte at different pH. Conditions: 3.06 mM imidazole and 0.1–1.5 mM sulfosalicylic acid; applied voltage = +15 kV; ambient temperature; injection for 15 s; current = 0.5–3 mA. The pH values tested were: (a) 4.52, (b) 5.00, (c) 5.42, (d) 6.00, (e) 6.52, (f) 7.04, (g) 7.53, (h) 8.03. Peaks (in ppm): 1, K^+ (5.9); 2, Na^+ (16.8); 3, Li^+ (8.73); 4, water dip; 5, HPO_4^{2-} (4.75); 6, F^- (9.92); 7, $HCOO^-$ (7.42); 8, ClO_3^- (9.96); 9, ClO_4^- (8.73). (Reproduced from Xiong and Li[148] by permission of Wiley–VCH.)

concentration was greater than 5.0 mM (with imidazole concentration higher than 4 mM) the migration times of more slowly migrating anions (e.g. ClO_3^- and ClO_4^-) increased rapidly. The authors concluded that a higher pH is advantageous for anion separations, but higher total electrolyte is deleterious to the same separations. Xiong et al.[148] further elaborated on this issue by utilizing an imidazole–benzenesulfonic acid system at two different ionic strengths (Figure 26). Although the electroosmotic flow generated under these two conditions was roughly the same, i.e. 79.5×10^{-5} and 75.4×10^{-5} $cm^2\,V^{-1}\,s^{-1}$ at pH 6.54 and 7.03, respectively, the migration times for anions were significantly increased at higher total IPD electrolyte concentration. Perhaps the counteracting effect of pH and total IPD electrolyte concentration should be considered when a simultaneous separation is performed.

4.4 Simultaneous Separation of 22 Anions and Cations in a Single Run

Using the third approach discussed early in section 4, Kuban and Karlberg[149] reported an impressive simultaneous CZE separation of cations and anions with IPD in less than 5 min (Figure 27). It is noteworthy that this is the highest peak capacity reported so far for the combined separation and IPD of these fast-moving ions. Unfortunately, using the same buffer recipe, transition metals and some alkaline earth metal ions (e.g. Ba^{2+}) cannot be analyzed because the cations tend to precipitate as

Figure 26 Separation results of the model sample mixture in imidazole–benzenesulfonic acid background electrolyte at different pHs and total electrolyte concentrations: (a) pH 6.54, 4.23 mM total electrolyte concentration (2.77 mM imidazole; 1.46 mM benzenesulfonic acid), 2.0 μA; (b) pH 7.03, 7.65 mM total electrolyte concentration (5.70 mM imidazole; 1.95 mM benzenesulfonic acid). Current = 3.5 μA; voltage = +29.0 kV; ambient temperature; detection at 214 nm; injection for 30 s; capillary = 40 cm (32 cm effective length) × 50 μm i.d. Peaks (in ppm): 1, K^+ (5.9); 2, Na^+ (16.8); 3, Li^+ (4.3); 4, water dip; 5, HPO_4^{2-} (4.4); 6, F^- (3.7); 7, $HCOO^-$ (4.3); 8, ClO_3^- (5.9); 9, ClO_4^- (4.3). (Reproduced from Xiong and Li[148] by permission of Wiley–VCH.)

hydroxides or react with the chromate ion. Alternative electrolytes therefore need to be developed for such ionic separations.

4.5 Selected Applications

Simultaneous determination of small cations and anions appears to be an efficient analytical method for ''total ion analysis'' in a variety of aqueous samples. Electrophoretic analysis of cations and anions in mud and milk samples was described by Kuban and Karlberg.[149] The dialyzed milk and mud samples were injected into the CE separation system and the total number of ions were analyzed in less than 5 min with RSD < 0.3% for migration times. In addition, good correlation was obtained

Figure 27 Separation of 22 anions and cations. Electrolyte: 6 mM 4-aminopyridine, 2.7 mM H_2CrO_4, 30 μM cetyltrimethylammonium bromide, pH 8. Indirect UV at 262 nm, with peak reversal. The linear baseline drift observed during the first 2 min was corrected for. Peak identification: (1) $S_2O_3^{2-}$, (2) Br^-, (3) Cl^-, (4) SO_4^{2-}, (5) NO_2^-, (6) NO_3^-, (7) WO_4^{2-}, (8) MoO_4^{2-}, (9) citrate, (10) maleate, (11) fumarate, (12) F^-, (13) HPO_4^{2-}, (14) Cs^+, (15) K^+, (16) NH_4^+, (17) HCO_3^-, (18) acetate, (19) Na^+, (20) Ca^{2+}, (21) Mg^{2+}, and (22) Li^+. between IC and capillary ion analysis data for simultaneous analysis of cations (K^+, Na^+, NH_4^+, Ca^{2+}, Mg^{2+}) and anions (Cl^-, SO_4^{2-}, NO_3^-, HCO_3^-) in tapwater and rainwater. Cations and organic acids in soft drinks (apple, orange, and grape juices) have also been determined using 1,2-dimethylimidazole–trimellitic acid with 6 mM 18-crown-6 as binary IPD reagent.[147] However, the matrix effect strongly influenced the migration of some organic acid (e.g. citrate). The researchers concluded that this is probably due to differences in the viscosity of the injected samples, which influenced the electroosmotic flow.

5 INDIRECT FLUORESCENCE DETECTION IN CAPILLARY ELECTROPHORESIS

Although the discussion thus far has concentrated on CZE/IPD, IFD also offers a means to detect analytes, even when they do not provide a signal at a given detector. In this type of detection, fluorescing ions rather than absorbing ions are used as the CZE electrolyte, and hence a large fluorescence background is always present when the excitation laser interacts with the solution flowing through the detection region. When the analytes appear in the detection region, displacement of the fluorophore ion by an analyte leads to a quantifiable change in the background fluorescence intensity that

translates to a negative peak. A simple form of fluorescence displacement is based on the displacement of charged analyte ions by fluorescing ions with the same charge on a regular equivalent-per-equivalent basis due to the requirement of electroneutrality. Other alternative displacement processes also exist, but charge interaction appears to be the most efficient. Similarly to indirect absorbance detection, IFD also can be considered as a universal detection scheme for CZE. It is pertinent to comment that the technique of capillary zone electrophoresis/indirect fluorescence detection (CZE/IFD) has been discussed in detail and in depth, in terms of basic principle and instrumentation, in some excellent monographs.[151–154]

5.1 Factors Influencing Indirect Fluorescence Detection Response

The sensitivity attainable with IFD depends on instrumental considerations. Although lamp-based fluorometers have been reported for IFD of alkali and alkaline earths ions,[155] inorganic anions,[146,156] and triorganotin compounds,[157] a more spectacular detection limit is observed when lasers are used as the excitation source.[151–154] However, unlike an absorption detector (where the background signal is very stable compared to the measured signal), background fluorescence signals in IFD fluctuate due to the inherent instability of lasers. In addition, fluorophores bleaching upon irradiation with the laser beam is a problem. Despite the high cost and complex operation of the lasers, a C_{LOD} that is an order of magnitude better (i.e. 10^{-7} M) than IPD is disappointing.

In addition to the instrumental considerations discussed above, detector response in IFD also depends on some chemical considerations. These include: concentration and type of the fluorescent reagent (also known as the IFD reagent); pH of the electrophoretic medium; and ionic strength of the buffer. According to Yeung and Kuhr,[151] IFD in CZE appeared to be more beneficial than the IPD method at a lower concentration of the visualization reagent. This is because the DR for IPD will decrease with a decrease in the following parameters: chromophore concentration; molar absorptivity; and pathlength (see Equation 1, section 1.3). Although the magnitude of fluorescence intensity also drops with a reduction in the aforementioned parameters, a high value of the DR over a wide range of concentration is still maintained in IFD due to the large signal generated from laser excitation. The observation of Yeung and Kuhr is consistent with recent reports published by a number of workers. For example, Andersson et al.[57] found that IFD is more attractive than IPD when the concentration of the fluorophore (e.g. salicylate) is less than 2 mM. Desbène et al.[158] also studied the response sensitivity of IFD by varying the concentration of fluorescein over the range 10^{-4}–10^{-8} M. Potassium *N*-butylbenzenesulfonate was used as a test sample because its electrophoretic mobility was closer to the mobility of fluorescein. The researchers reported the best compromise concentration for IFD sensitivity to be 10^{-5} M fluorescein sodium salt.

As outlined by Garner and Yeung,[154,159] there are five important considerations in the selection of IFD reagents:

1. The fluorophore that should serve as a detection reagent should have a large molar absorptivity for the excitation wavelength available. This is critical if a laser rather than a lamp is used as an excitation source.
2. The quantum efficiency of the fluorophore should be as high as possible.
3. The fluorophore should be soluble and inert in the running CZE solvent system.
4. For the optimum value of TR (Equation 1, section 1.3) the fluorophore should be fully charged with a preferable charge of unity, and present at as low a concentration as possible.
5. The fluorophore should have minimum adsorption on the walls of the capillary because any adsorbed material will not participate in the charge displacement process.

Based on these considerations, the authors first studied fluorescein as the IFD reagent for the detection of aspartic acid and glutamic acid[161] after their separation by CZE. Even without stabilizing the laser source, mass limits of detection (ca. 2 fmol) were reported for the two amino acids.

The sensitivity of IFD is also dependent on the stability of the fluorescence reagent at a given pH; therefore, it is important to select a pH range where the fluorescent intensity of the IFD reagent is constant. Garner et al.[159] first studied the effect of pH on the fluorescence signal of fluorescein. They reported that an increase in pH from 7 to 9 resulted in a very unstable baseline, presumably due to the interaction of fluorescein with the capillary wall. The researchers then switched to Coumarin 343, a fluorophore with good water solubility, high molar absorptivity (2×10^4 at an excitation wavelength of 242 nm) and high quantum yield. Unlike fluorescein, a relatively high pH stability of this coumarin was found, with some degradation above pH 11.5. The authors demonstrated excellent mass sensitivity by detecting fructose at the 2 fmol mass level. This was accomplished using 5-μm i.d. capillaries, which is a very difficult task with lamp sources. In the same report, Garner et al.[159] described why IPD and IFD analyses of carbohydrates

are limited by Equation (10):

$$TR = \frac{\alpha[\text{sugar}]}{[FL^-] + [OH^-]} \quad (10)$$

According to Equation (10), at a constant concentration of chromophore or fluorophore [FL^-] and carbohydrate [sugar], the TR is affected by the values of α (the fraction of carbohydrate in ionized form) and [OH^-] (the concentration of hydroxide in solution). Thus, α in the numerator and [OH^-] in the denominator are competing functions of pH. Consequently, the total TR (TR_{total}) goes through a maximum if it is plotted as a function of pH. The maximum in this plot is the optimal pH for IPD or IFD. However, carbohydrates that have a strong negative charge at lower pH (e.g. phosphorylated and sulfated sugars) are best optimized at lower pH where the effect of hydroxide ion in Equation (10) is minimized. Desbène et al.[158] reported that the fluorescence intensity of fluorescein first increases as the pH is raised from 4 to 8, and plateaus only in the highly basic pH range of 8–10. For optimum detection sensitivity the authors recommend a pH of 9.2, where the fluorescence intensity of fluorescein was a maximum and the electroosmotic flow was stabilized. This result obtained by Desbène et al.[158] is in disagreement with the earlier report of Garner et al.,[159] who found an erratic baseline when

Figure 28 Effect of pH on the separation, sensitivity, and direction of the fluorimetric signal of a mixture of 21 inorganic anions and organic acids. Electrolyte consisted of 20 μM FMN in 100 mM H_3BO_3 and 2 mM DETA, adjusted to various pH values with 1 mM NaOH. All anion peak concentrations are 2 mg L^{-1} for inorganic anions and 5 mg L^{-1} for organic acids. Peaks: (1) bromide, (2) chloride, (3) nitrite, (4) nitrate, (5) chromate, (6) sulfate, (7) oxalate, (8) molybdate, (9) tungstate, (10) malonate, (11) fluoride, (12) fumarate, (13) formate, (14) succinate, (15) malate, (16) citrate, (17) tartrate, (18) phosphate, (19) hypophosphate, (20) phthalate, (21) carbonate. Pressure injection for 4 s at pH 7.8–8.6 and for 8 s at pH 9.0; voltage of −15 kV applied for separation; current varied from 7.0 to 41 μA. (Reproduced with permission from Shamsi et al.[160])

fluorescein was used at pH 9.0. The discrepancy may be due to the fact that a temperature-controlled commercial CE system equipped with a stabilized laser source was employed in the former study. Very recently, Shamsi et al.[160] reported a loss in S/N for inorganic anions using flavin mononucleotide (FMN) fluorophore at pH values greater than 8.0. Because FMN shows a stable response in the pH range of 3.5–8.0,[161] one would expect a reduction in fluorescence response at the weakly alkaline pH values. The situation was a bit more complicated, however, when peak direction was switched, i.e. positive peaks were observed at pH values such as 8.6 or 9.0. Probably the replacement of OH^- as well as FMN by the sample anions could cause a temporary localized decrease in pH. At pH 8.6 or 9.0, this may lead to a fluorescence increase, whereas at pH 7.8 or 8.2 the fluorescence remains quite constant. Therefore, positive peaks (decreased fluorescence) of inorganic anions and organic acids were observed at pH 7.8 and 8.2 and the baseline noise was quite low (Figure 28a,b). In contrast, negative peaks (increased fluorescence) were observed at pH values of 8.6 and 9.0 (Figure 28c,d) due to the more important decrease in OH^-. The optimum pH for the best S/N for anions was found to be around 8.0 or lower, where preliminary replacement of FMN by the sample anions causes the signal change.

Finally, the ionic strength of the CZE buffer was also shown to play a major role in evaluating the sensitivity of IFD.[158] In fact, buffers of low ionic strength can be very beneficial because the Joule heating induced by the low operating currents is minimized. However, distortion of the analyte zone with buffers of very low ionic strength is possible. Figure 29 illustrates the reduction in S/N of Li^+ and K^+ as a function of the ionic strength of borate buffered at pH 9.2. It is clear that IFD sensitivity was a maximum at a sodium borate concentration of 10 mM. A 10-fold improvement in sensitivity of the cations was observed when the sodium borate concentration was further decrease from 10 to 2.5 mM.

5.2 Applications of Indirect Fluorescence Detection for the Analysis of Ionic Compounds

Although a wide variety of UV-absorbing chromophores are now available for both cation and anion analysis by CZE/IPD, little work has been done to characterize IFD electrolytes for CZE of ionic analytes. This is for two major reasons: the number of fluorophores that can serve as a detection reagent is smaller than the number of chromophores, and fluorophores that have strong emission are large organic molecules with low mobility, resulting in poor selectivity for high-mobility inorganic anions.

Figure 29 Evolution of S/N, in the hydrodynamic injection mode, as a function of the ionic strength of the electrolyte in the mobile phase. Operating conditions: fused-silica capillary 57 cm × 75 µm i.d.; applied voltage = 10 kV; temperature = 30 °C; sample mixture of $LiNO_3$ (10^{-4} M) and KNO_3 (10^{-4} M); electrolyte, $Na_2B_4O_7$ (pH 9.2); fluorescein concentration, 10^{-5} M; fluorimetric detection ($\lambda_{exc.} = 488$ nm, $\lambda_{detect.} = 520$ nm). (Reproduced with permission from Desbène et al.[158])

5.2.1 *Capillary Zone Electrophoresis/Indirect Fluorescence Detection of Anionic Compounds*

In 1988, Kuhr et al. in Yeung's laboratory first introduced IFD for the CZE analysis of underivatized amino acids, proteins, and nucleosides.[162,163] Later, Yeung's laboratory further evaluated IFD for an extensively large number of analytes. The anionic compounds for which successful CZE/IPD was developed include inorganic anions,[164] nucleotides,[165] sugars[159] and tryptic digests,[165] lactate and pyruvate,[166] and more recently free cyanide and related compounds.[167]

Salicylate was the IFD reagent reported for determination of seven common inorganic anions in less than 5 min.[164] Using a 0.25 mM equimolar mixture of salicylic acid and sodium salicylate at a pH of 4.0, detection limits in the submicromolar range (1×10^{-7} M) were obtained. The authors found that the same IFD reagent is also useful for the separation of 12 nucleotides in ca. 6 min.[164] However, in order to reduce the electroosmotic flow, the salicylate concentration was increased to 1.0 mM and the pH was decreased to 3.5. In a related paper, Garner and Yeung[159] were able to resolve three sugars (glucose, sucrose, fructose) and seven underivatized amino acids (phenylalanine, alanine, leucine, serine, glutamic acid, aspartic acid, proline) using 1 mM coumarin at pH 11.5

Figure 30 Electropherograms for the analysis of red blood cells. The numbers 6, 11, 10, and 23 refer to the chronological order of the experiments. Peaks 1 and 2 refer to lactate and pyruvate, respectively. (Reproduced with permission from Xue and Yeung.[166])

and 9.5 respectively. Although the authors determined that the optimum detection pH for the CZE separation of carbohydrates would be 11.65 (based on Equation 10), still a pH of 11.5 was used to generate the electropherogram of sugars. This is because they found significant degradation of coumarin as they increased the pH toward the optimum value. A more sophisticated approach was described later by Xue et al. in Yeung's laboratory.[166] The authors applied IFD for the quantitation of the major anions (lactate and pyruvate) within the single erythrocytes at the femtomole level (Figure 30). Unfortunately, it was difficult to obtain the migration time precisely (i.e. the RSD for migration time change was up to 20%). Consequently, a migration time ratio method was used that provided much improved precision (i.e. 3% RSD). Marti et al. in collaboration with Yeung's group[167] have developed an IFD method after CZE separation of free cyanide (CN^-) and related inorganic anions (CNO^-, SCN^-, and NO_3^-). Using 1 mM fluorescein at pH 11, the CZE separation and IFD of CN^- was achieved in less than 4 min without any interferences from common inorganic anions (Cl^-, SO_4^{2-}, and HCO_3^-). The C_{LOD} of CN^- was determined to be 5×10^{-6} M, which was close to the expected theoretical value (Equation 1, section 1.3).

Fluorescein as an IFD electrolyte was also utilized by Chao et al. for the separation and IFD of 11 priority phenols.[168] Nearly baseline separation of 11 phenols was achieved in ca. 14 min at pH 9.9, with 15 mM borate containing 1 mM fluorescein. The method was applied successfully to the analysis of a National Institute of Standards and Technology standard reference material (NIST SRM 184) and priority phenols in industrial wastewaters.

Although the use of lasers for IFD began as early as 1988, substantial interest has developed recently due to the commercial availability of a laser-induced fluorescence detector for CE. Desbène et al.[158,169] in a series of two papers have advocated the use of fluorescein for this commercial system. In the first paper,[158] the authors analyzed a mixture containing three transition metals (Fe^{3+}, Zn^{2+}, and Cu^{2+}), three alkaline earths (Ba^{2+}, Ca^{2+}, and Mg^{2+}), and two alkali metals (Li^+ and K^+). Because the use of fluorescein provides maximum sensitivity at basic pH, a complexing agent such as ethylenediaminetetraacetic acid was added to transform transition metal and alkaline earth metal cations into anionic chelates, so that their interaction with the capillary could be minimized at basic pH. As expected, Li^+ and K^+ eluted before the electroosmotic flow, whereas the six metal chelates eluted after the electroosmotic flow under the optimized conditions of 10 μM fluorescein and pH 7.5. They rationalized the observations based on the treatment developed by Ackerman et al.,[18] who have shown that if the absolute mobility of the analyte is smaller than the mobility of the counterion associated with the chromophore or fluorophore, then negative peaks will be observed, and vice versa. Thus, the observed positive peak for K^+ and negative peak for Li^+ agree with the theory of Ackerman et al. However, it was not very clear as to why the Fe^{3+} chelate provided a negative fluorescent peak whereas Ba^{2+}, Ca^{2+}, Mg^{2+}, Zn^{2+}, and Cu^{2+} chelates showed positive peaks.

In a second paper Desbène et al.[169] separated two mixtures – alkanesulfonates (C_1-C_{10} SO_3^-) and alkyl carboxylates (C_1-C_{12} COO^-) – under aqueous conditions using 10 μM fluorescein and 5 mM $Na_2B_4O_7$ at pH 9.2 in about 4 and 7 min, respectively. However, the analysis of fatty acids longer than C_{12} required the use of organic solvents (2-propanol, ethanol, or acetonitrile). The authors found no decrease in background fluorescence, irrespective of the solvent used, until the percentage of organic solvent was lower than 40% (v/v). Beyond this limit, baseline fluctuations and noise were increased substantially. They were able to achieve detection limits as low as 700–800 ppb, and the system was used to establish calibration curves and response coefficients for IFD.

Several other groups have continued to extend the utility of fluorescein. For instance, Wang et al. evaluated the feasibility of using nonaqueous solvents in CZE with IFD.[170] C_6-C_{24} FFAs differing by only one carbon atom were separated and detected in a highly alkaline methanol–acetonitrile system in combination with fluorescein as the IFD reagent. Similarly, Huang et al.[171] used 1.5 mM fluorescein at pH 9.8 for effective separation and detection of five arsenic compounds (arsenite, arsenate, monomethylarsonate, dimethylarsonate, and phenylarsonate) using CZE with IFD in 8 min. Detection limits in the 0.04–0.16 mg mL^{-1} range were

reported. Unfortunately, the developed method could not be applied for the analysis of arsenic in groundwater, due to matrix effects.

The CZE/IFD method using salicylate reagent was compared to CZE with direct and indirect UV detection for the determination of isoprenyl pyrophosphate.[57] The researchers reported that IFD was the most suitable detection method that provided the lowest C_{LOD} (0.5 μM) and highest separation efficiency (600 000) compared to direct or indirect UV detection. However, the C_{LOD} was still not low enough to allow analysis of dilute samples of rat liver.

Very recently, the novel IFD reagent FMN, also known as riboflavin-5′-phosphate, was developed in our laboratories for indirect laser-induced fluorescence detection (ILIFD) of a wide spectrum of anionic compounds.[160] Unlike fluorescein, FMN provided strong fluorescence at both acidic and basic pH values. A CZE separation of 21 inorganic and organic anions in about 20 min was possible for the first time with ILIFD. Figure 31 shows the separation of 21 inorganic anions and organic acids at 5 μM and 30 μM FMN. At 100 μM baseline drift was substantial and the S/N decreased (electropherogram not shown). The optimum concentration of FMN was found to be 30 μM because of a better S/N and a reasonable baseline drift. In addition, the use of methanol provided improved resolution and facilitated simultaneous separation and universal IFD of aliphatic and aromatic anionic surfactants. Using pressure injection, the C_{LOD} was 20–30 μg L^{-1} for inorganic anions, 40–50 μg L^{-1} for organic acids, 250–500 μg L^{-1} for P_n, and 500–1000 μg L^{-1} for alkyl sulfates. C_{LOD} was optimized further by at least twofold with electrokinetic injection, and the developed CZE/IFD was applied to the simultaneous analysis of ethoxylated lauryl sulfate and lauryl sulfate in a commercial shampoo in less than 10 min.

Figure 31 Effect of FMN concentration on separation, selectivity, and baseline stability of a mixture of 21 inorganic anions and organic acids. Electrolyte consisted of 5 μM (a) and 30 μM (b) FMN in 100 mM H_3BO_3, 2 mM DETA, pH 7.8 buffer; pressure injection for 4 s; voltage of −15 kV applied for separation. Current varied from 6.5 to 8.0 μA. Peak identification is the same as in Figure 28. RFU = relative fluorescence units. (Reproduced with permission from Shamsi et al.[160])

5.2.2 *Capillary Zone Electrophoresis/Indirect Fluorescence Detection of Cationic Compounds*

Unlike anionic separations, IFD of cations by CZE is largely unexplored. A literature survey indicated that the cationic compounds for which successful IFD has been reported include only a few organic cations (alkylamines, alkanolamines, tetraalkylammonium, and alkyltins).[165,175] Quinine sulfate excited with an argon ion laser at 350 nm was the first cationic fluorophore studied for the analysis of some alkali and alkaline earth metal ions and several substituted amines.[165] The optimized system used included 0.38 mM quinine sulfate as IFD reagent and 0.58 mN H_2SO_4 to create a pH of 3.7. Because quinine sulfate is a relatively low-mobility cation, the later-eluting peaks (diethylamine, diethanolamine, tetraethylammonium, and trishydroxyaminomethane) were taller and sharper than those for early-eluting ions (ammonium or dimethylammonium). This pattern of peak profiles in IFD was consistent with the theory developed on peak shapes for CZE/IPD.

In a recent paper, Church et al.[172] have also demonstrated the potential of quinine sulfate in combination with α-HIBA for the separation and ILIFD of lanthanide ions, including La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+}, and Eu^{3+}, in the low-ppb range (6–11 μM). An impressive C_{LOD} was possible due to the combination of electrokinetic injection and transient isotacophoresis, which enabled the metal cations to stack into more concentrated zones.

Underivatized amino acids as positively charged ions were investigated using a semiconductor laser with an excitation source of 670 nm.[173] Three potential dyes (methylene blue, rhodamine, and oxazine 750) that can be excited at 670 nm were evaluated as IFD electrolytes. Among the three dyes studied, methylene blue was found to be the most suitable due to its lesser adsorption on the capillary surface. At a high pH value of 11 the adsorption of methylene blue was reduced further, but the fluorescence intensity was substantially decreased at this pH. Therefore, an acidic pH of 3.80 was used to separate and detect the two amino acids (glycine and proline) via CZE/IFD in ca. 15 min.

A small cationic fluorophore, 2-AP, was investigated for ILIFD of sodium and potassium at attomole levels. Li

and Yeung[174] reported that the difficulty associated with the determination of these inorganic cations at such low levels is due to their contamination in the environment. After detailed studies, it was realized that particulate contamination was the primary source of interference for the cations. This is because one dust particle contains femtomoles of sodium and potassium because as the particle is inadvertently injected false peaks are obtained. After optimizing the procedure for cell samples they reported the mass LOD of potassium and sodium to be 110 and 70 amol respectively.

The first successful use of a lamp-based source for IFD in CZE was accomplished by Bächmann et al.[155] for the determination of ammonium and alkali and alkaline earth metals by means of an inexpensive fluorescence detector. This accomplishment was carried out using cerium(III) fluorophore excited at 251 nm, with emission collected at a 345-nm cut-off filter. The authors found that in cerium(III) sulfate solution the effective positive charge of Ce^{3+} is smaller than that in solutions of cerium(III) nitrate and chloride. Their observation was in agreement with the lower values of effective mobilities observed for cations separated by CZE using cerium(III) sulfate compared to cerium(III) nitrate. In addition, the authors recommended cerium(III) nitrate and chloride salts as suitable IFD electrolytes for the measurement of fast-moving cations (e.g. Cs^+, NH_4^+, K^+), whereas cerium(III) sulfate was suggested as a better electrolyte for slow-moving cations (e.g. Li^+). Some metal cations in the cola beverage were profiled, with C_{LOD} reported in the low micromolar range (0.1–0.3 μM).

Finally, Lee and Whang have recently introduced 6-aminoquinoline as the IFD reagent for trialkyltin compounds.[175] A CZE separation of trimethyl-, triethyl-, tripropyl-, tributyl-, and triphenyltin with IFD using a nonlaser-based fluorometer was achieved in less than 16 min. A C_{LOD} in the range 8–18 μM that corresponds to a mass LOD of 80–180 fmol was obtained. The authors pointed out that the lamp-based IFD is simple and cost-effective, with the added advantage of a wide range of wavelengths available for excitation compared to the laser-based IFD.

5.3 Applications of Indirect Fluorescence Detection for the Analysis of Neutral Compounds

Although MEKC can be used easily to separate neutral compounds, indirect detection of these compounds is somewhat problematic. This is because the charge displacement cannot be used to displace the absorbing or fluorescent ion from the analyte zone. One of the most elegant solutions to the problem was provided by Amankawa and Kuhr,[176] who introduced the use of anionic SDS as complexing agent to the positively charged

Figure 32 Electropherogram showing the separation of a mixture of alchols by MEKC and IFD. Buffer was composed of 0.50 mM quinine sulfate in 100.0 mM SDS aqueous solution, pH 6.8. Instrumental parameters were as follows: capillary was 80 cm fused-silica (60 cm to detector), 50 μm i.d. and 360 μm o.d., excitation wavelength = 325 nm; voltage = 25 kV (current = 26 μA); temperature = 30 °C; sample was composed of 0.06% v/v (7.0 mM) of each component and was injected for 1.0 s by applying a 5-in. Hg vacuum to the cathodic compartment. Peak identity is as follows: (a) 2-propanol, (b) 1-propanol, (c) 2-butanol, (d) 1-butanol; (e) 2-methyl-1-propanol. (Reproduced with permission from Amankawa and Kuhr.[176] Copyright 1991 American Chemical Society.)

quinine fluorophore. The authors observed enhanced fluorescence of the quinine ion because of its ion-pairing with the micelle, leading to a large fluorescent background signal. Upon injection, the nonionic analyte enters the micelle and can disturb the micelle–fluorophore complex. Thus, the background fluorescence is decreased, resulting in a negative peak. Despite the enhancement of the background fluorescence intensity of quinine sulfate, no significant shift in the maximum of the quinine emission was observed in the presence of SDS. A pH of 6.80 with 0.50 mM quinine sulfate and 100 mM SDS provided the separation of a mixture of five aliphatic alcohols in less than 8 min (Figure 32). The authors were able to detect phenols with much higher sensitivity (about five times) than aliphatic alchols, even though the latter group of solutes eluted much earlier than the former. This indicated that the phenolic compounds have a relatively stronger quenching effect and can disturb the micelle–fluorophore complex more efficiently.

Recently, Smith et al.[177] evaluated three IFD reagents (quinine sulfate, 8-anilinonaphthalene-1-sulfonic acid and *N*-phenylnaphthylamine (PNA)) in combination with a

nonionic surfactant (decanoyl-*N*-methylglucamide) and borate. The authors observed that PNA, the most hydrophobic fluorophore, provided the best sensitivity for IFD. Similarly to the observation of Amankawa et al.,[176] the results obtained by Smith et al. also showed an increase in IFD response with an increase in capacity factor of the solute. Figure 33 shows a typical electropherogram of an alkyl phenyl ketone homologous series as evidence for this observation. In addition, Smith et al. demonstrated a linear relationship between peak height and capacity factors, in contrast to a nonlinear behavior found by Amankawa et al.

Kennedy et al.[178] have applied MEKC for the IFD of high explosives. Fluorescein and rhodamine B were evaluated as potential fluorophores. In general, the authors found rhodamine B to be a better IFD reagent than fluorescein because the former resulted in a stable baseline and greater sensitivity. Despite the fact that some explosives could be detected at concentrations as low as 6×10^{-6} M, overall detection sensitivity was poor. The researchers attributed this lack of sensitivity to the laser instability, and suggested the use of a laser power stabilizer as a possible solution to laser noise and baseline drift.

Figure 33 Electropherogram of alkyl phenyl ketone homologus series. Experimental conditions: running electrolyte, 100 mM borate containing 50 mM decanoyl-*N*-methylglucamide (MEGA 10) and 0.5 mM PNA, pH 10.0; capillary, 50-cm (detection point) untreated fused-silica, 80 cm (total length) × 50 mm i.d.; voltage = 15 kV; excitation wavelength = 365 nm; emission wavelength > 400 nm. Analytes: (1) acetophenone ($n = 0$), (2) propionophenone ($n = 1$), (3) butyrophenone ($n = 2$), (4) valerophenone ($n = 3$), (5) hexanophenone ($n = 4$), and (6) heptanophenone ($n = 5$). Concentration injected: 1 mM of each. (Reproduced with permission from Smith and Rassi.[177])

Fuchigami and Imasaka accomplished[179] IFD of flavin adenine dinucleotide and deoxyadenosine monophosphate following their MEKC separation. Methylene blue was the IFD reagent and a semiconductor laser emitting at 670 nm was used as the excitation source. This indirect fluorescence detection/micellar electrokinetic chromatography (IFD/MEKC) method also provided lower mass detection limits (fmol), by several orders of magnitude, than those reported for an HPLC-based method using the same semiconductor laser fluorescence detection.

6 OTHER INDIRECT DETECTION MODES

6.1 Indirect Chemiluminescence Detection

The general indirect route to chemiluminescence detection is to use a nonchemiluminescence analyte that will interfere or suppress a chemiluminescence reaction. Thus, inverted or negative peaks are observed if the analytes are detected indirectly due to a decrease from a constant chemiluminescence background. Liao et al. were probably the first to demonstrate the successful use of ICLD in CE.[180] It is well known that the chemiluminescence reaction of luminol with hydrogen peroxide is catalyzed by Cu(II), and the chemiluminescence response is proportional to the concentration of free Cu(II). Liao et al. showed that in the absence of analytes a high and constant chemiluminescence background is maintained when Cu(II) is continuously mixed with the luminol and H_2O_2 in the reaction/detection capillary at pH 10.0. After the CE separation, analytes (e.g. amino acids) enter the reaction zone and complex with Cu(II), decreasing the concentration, and catalytic activity of the free Cu(II). As a result of the postcapillary formation of Cu(II)–amino acid complexes, chemiluminescence intensity is decreased, resulting in a negative peak.

In a subsequent paper,[181] the same authors examined a number of parameters of the ICLD system, including buffer concentration, chemiluminescence reagent concentration, catalyst concentration, α-cyclodextrin concentration and pH. It was found that the luminol chemiluminescence reaction needs an alkaline pH in the range 9–11. A comparison of high-pH buffers (borate, dibasic sodium phosphate, and carbonate) indicated that 15 mM carbonate at pH 10.0 provides the optimum chemiluminescence emission, leading to the best sensitivity for ICLD of amino acids. They suggested that the luminol/H_2O_2 concentration should not exceed 5 mM : 25 mM. This is because a higher concentration of luminol decreases the chemiluminescence intensity. On the other hand, an increase in the concentration of H_2O_2 increases the chemiluminescence intensity. However, bubble formation in the buffer reservoir was a problem due to unsteady

Figure 34 Electropherogram of 10 amino acids with ICLD. Electrophoretic buffer: 15 mM carbonate–5 mM luminol–25 mM H_2O_2, pH 10.0. Separation capillary, 50 μm i.d., 50 cm long; sample injection for 2 s at 21 kV; sample concentration, 1 mM each of analyte. Peaks: 1 = arginine, 2 = proline, 3 = valine, 4 = leucine, 5 = glutamine, 6 = asparagine, 7 = serine, 8 = cysteine, 9 = glutamic acid, 10 = aspartic acid. (Reproduced with permission from Liao et al.[180])

electrophoretic current and a substantial increase in baseline noise. They also observed that the maximum S/N for ICLD is ca. 30 μM $CuSO_4$. Tartaric acid, which prevented the formation of $CuCO_3$ or CuOH in alkaline pH was added as an auxiliary reagent to Cu(II). The optimization procedure discussed above resulted in CZE separation with ICLD of 10 amino acids (Figure 34). However, a complete baseline separation of 10 amino acids was not successful. Use of 50 mM α-cyclodextrin and 5% methanol led to improved resolution only at the expense of detection sensitivity. One of the major limitations of ICLD is the sigmoidal nature of the calibration curve, which limits the dynamic range to only about two orders of magnitude. Although, the mass LODs of amino acids was in the 100–140 fmol range, it depended mainly on the formation constants of amino acids with Cu(II). Application of the developed ICLD method was demonstrated by analyzing glutamate in a commercial drink.

A similar ICLD method for catecholamines and neurotransmitters has been studied recently by Zhang et al.[182] The authors found that Co(II) is a better catalyst for chemiluminescence reaction compared to Cu(II). The rationale was based on the fact that the Co(II) possesses a shorter half-life (time required to obtain maximum chemiluminescence intensity), with a fast kinetic reaction leading to a stronger chemiluminescence intensity. On the other hand, the use of Cu(II) with a longer half-life may result in weaker chemiluminescence intensity. Zhang et al. were able to resolve and detect four catecholamines (catechol, epinephrine, norepinephrine, and dopamide) by employing 10 mM SDS, 1 mM luminol and 5 mM borate (as separation electrolytes), with 5 mM H_2O_2–5 μM Co(II) as the chemiluminescence reagent. In addition, mass LODs in the range 22–87 fmol for catecholamines and 9–250 fmol for six amino acids were reported. These detection limits were about two or three orders of magnitude lower than those obtained in HPLC with ICLD.

In summary, the use of ICLD in CE can provide femtomole mass detection limits but it suffers from two major shortcomings: the method of ICLD is useful only for a few organic compounds, therefore one area of key importance is the development of appropriate recipes for electrophoresis buffers and chemiluminescence reagents to separate and detect a variety of non-chemiluminescence inorganic and organic species (metal ions, peptides, proteins and cyclic nucleotides); and in the present design of the CE/chemiluminescence interface it takes ca. 7 s for the solution to flow from the tee to the reaction cell. As a result, the chemiluminescence catalyzed by metal ions decays before it can be used to provide a sufficient background chemiluminescence signal for indirect detection. Hence, the design of a new and improved CE/chemiluminescence interface should help to decrease the half-life required for maximum chemiluminescence signals, leading to lower LODs.

6.2 Indirect Electrochemical Detection

Electrochemical principles appropriate for indirect detection in CE include potentiometry, amperometry, and conductivity. In recent years, only the latter two detection methods have been implemented successfully in the indirect mode in CE.

6.2.1 Indirect Amperometric Detection

The general indirect route to amperometric detection is to use an electrophore-competing ion that is itself electroactive, and to monitor the changes in the concentration of this electroactive species as analyte ions are eluted from the capillary. The earliest and perhaps the only example reported so far in the literature is likely to be the work of Olefirowicz and Ewing,[183] who used 3,4-dihydroxybenzylamine (DHBA) as an electrophore

to monitor the emergence of sample ions by registering a decrease in the background current. The authors used 0.1 mM DHBA and a working electrode held at a constant potential of 0.7 V vs. SSCE, taking advantage of the pH-dependent oxidation behavior of DHBA to orthoquinone as shown in Scheme 1:

Scheme 1

A high and constant background current was obtained due to continous oxidation and a steady flow of DHBA. After the analytes were separated by CE and passed through a detector region, a lower level of oxidizable species was observed in the detection zone. The background current thus decreases, resulting in a negative peak. It is noteworthy that the electrophore needs to be present at a very low concentration only, and may therefore be used in conjunction with a buffered system to achieve reproducible migration times. Figure 35 shows the separation of three nonelectroactive cationic amino acids and three nonelectroactive cationic dipeptides using 2-morpholinoethanesulfonic acid buffered at pH 5.65 containing 0.01 mM DHBA, giving a mass LOD as low as 380 amol for the amino acid arginine.

6.2.2 Indirect Conductivity Detection

Although CE with direct conductivity detection in both suppressed[186,187] and nonsuppressed[188,189] mode is documented, little work has been done with ICD. Similarly to other indirect methods, ICD in CZE is achieved when the carrier electrolyte has a higher level of background conductivity than the analytes. This means that in order to achieve a sensitive signal for ICD, the conductivities of the carrier and electrolyte co-ions have to differ significantly. On the other hand, CZE separation requires that the mobilities of the analyte and carrier ions should be close to avoid excessive peak spreading. These two contradicting requirements can be compensated partly by increasing the ionic strength of the carrier electrolyte.[188] In general, for sensitive detection of high-mobility inorganic anions and cations a low-mobility carrier electrolyte with direct conductivity detection is preferred. In contrast, sensitivities of large cations and anions with low electrophoretic mobilities are much better with ICD.

One of the early reports of ICD in CE is by Gallagher and Danielson.[189] To detect low-mobility anionic surfactants (C_6–C_{12} SO_3^-) and cationic surfactants (tetraethyl-, tetrabutyl-, 2-chloroethytrimethyl-, and tetrahexylammonium), a wide range of inorganic cations and anions were

Figure 35 Electropherogram of amino acids and peptides with indirect amperometric detection on a 9-mm i.d. capillary; buffer, 0.01 mM dihydroxybenzylamine–0.025 M morpholinoethanesulfonic acid (pH 5.65); 97-cm separation capillary; 1.0-cm detection capillary; injection for 1 s at 20 kV; separation voltage = 20 kV. Peaks: A = 8.5 fmol Lys; B = 8.2 fmol Arg; C = 7.4 fmol His; D = 7.0 fmol Arg-Leu; E = 6.4 fmol His-Gly; F = 5.8 fmol His-Phe; S = system peak. (Reproduced with permission from Olefirowicz and Ewing.[183])

evaluated as ICD electrolytes. The authors found that the S/N for anionic surfactants using F^- as an ICD electrolyte was about five times larger than those obtained with SCN^-, Br^- or Cl^-. Moreover, the S/N for cationic surfactants using NaCl was higher than when using LiCl. Hence, NaF was found to be the best ICD electrolyte. The simultaneous separation and ICD of both cationic and anionic surfactants using the optimized concentration of 30 mM NaF is shown in Figure 36. For three replicate injections, the RSD of the peak height for cationic surfactant ranged from 0.6 to 2.8%, whereas for anionic surfactants it ranged from 0.07 to 1.1%. A typical detection limit attained by this method was ca. 6 mg L^{-1}

Figure 36 Electropherogram of a 37.5 ppm anionic and cationic surfactant mixture. Electrolyte: 10 mM NaF, 1 mM TEA, 90% water, and 10% methanol. ClETMA, chloroethyltrimethylammonium; TBA, tetrabutylammonium; THA, tetrahexylammonium; EOF, electroosmotic flow. (Reproduced with permission from Gallagher and Danielson.[189])

(31.9 μM for C_6 SO_3^-), which was not as low as that reported for IPD.

Lucy and Wu[190] recently confirmed that ICD is most sensitive for low to medium-mobility analytes. For example, using bromide, acetate, and formate counterions, ICD after CZE separation of C_6–C_{12} SO_3^- was possible. Lucy and Wu also showed that the response of conductivity detection is linear for more than two orders of magnitude (5×10^{-6}–5×10^{-4}), with C_{LOD} as low as 1 μM for C_6 SO_3^-. Owing to similarities in conductivity and electrophoretic mobility, a response equation was developed and applied to show that the possibility exists for a universal calibration in conductivity detection.

Very recently, Fracassi da Silva and do Lago designed an oscillometric conductivity detector for CE.[191] Using this detector, ICD of quaternary ammonium salts was accomplished with potassium acetate as the CZE buffer. The peak sensitivity was found to be proportional to the migration time, e.g. tetramethylammonium ion eluted first and tetrabutylammonium ion eluted last, providing C_{LOD} values of 10.4 and 4.2 μM, respectively.

The near-infrared (NIR) region (600–1100 nm) offers several advantages in comparison with the conventional ultraviolet/visible (UV/VIS) region for spectroscopic measurements and detection. The lack of commercial instrumentation impeded the development of NIR techniques for years. The advent of inexpensive photodiodes and diode lasers used widely by the telecommunication industry gave the necessary impetus for development of analytical NIR techniques. This article describes the fundamental properties of NIR fluorophores and absorbers and provides a comparison with conventional UV/VIS dyes. The various analytical applications developed in the past decade that have utilized the advantages offered by this region are described with a particular emphasis on bioanalytical uses.

1 INTRODUCTION

The current interest in development of new techniques for analysis is largely attributed to limitations of the more conventional instrumental methods. Classical biomolecule identification usually involves separation of a complex mixture of biological molecules followed by tests for identification of the separated fractions. No single test provides definitive identification of an unknown biomolecule, hence a complex series of tests are required. Such processes are time-consuming and cannot be carried on a reasonable timescale needed in clinical laboratories. These obstacles and the desire to attain adaptability to primitive field test conditions have prompted many researchers to explore modern alternatives to classical instrumental procedures. Most of these modern analytical tools are characterized by rapid data acquisition and data reproducibility which is due to coupling with computer-aided instrument control, data recording and interpretation. A number of modern instrumental techniques have been applied to the identification of biomolecules. These well-established methods include high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), circular dichroism (CD), gas chromatography (GC), and mass spectrometry (MS). Many of these techniques have also been adapted for field applications. Most of these techniques conventionally have been applied in the UV/VIS region. However, the NIR region offers several advantages over the conventional UV/VIS region.

Sir William Herschel, the English astronomer, discovered the NIR region (600–1100 nm) at the beginning of the 19th century[1] by using a prism and a thermometer; however, this region of the electromagnetic spectrum did not receive much attention until the advent and recent availability of inexpensive light sources, such as diode lasers and detectors such as photodiode and avalanche photodiode (APD) detectors. The 600–1100-nm region corresponds to an energy range of 48–26 kcal mol^{-1}. Atomic and molecular transitions in this long-wavelength region are processes that require relatively low-energy photons, because the ground- and excited-state species are close in energy. As a result, several classes of molecules, such as polymethine and phthalocyanine (Pc) dyes, and certain elements, such as ruthenium and osmium, require a moderately low energy input to produce spectroscopically measurable electronic transitions.

Owing to its sensitivity and selectivity, fluorescence is used as a major analytical tool in the identification of target molecules of interest. Typically, this involves using fluorophores as reporter molecules or labels. Background fluorescence from components other than the

Figure 1 Visible to NIR region and possible interferences from native fluorescence.

fluorophore of interest decreases the sensitivity of detection in solution. In biological systems, this background fluorescence is typically from the autofluorescence of certain biological components. Similar problems are encountered with environmental samples. Typical background fluorescence occurs at all wavelengths in the visible region and at various intensities depending on the concentration of interfering molecules present in the sample (Figure 1). Elimination of background fluorescence is essential where the undesired components are not separated and fluorescence must be detected in the presence of intervening molecules. In fluorescence analysis, excitation light can be scattered from interaction with various types of molecules at the surfaces of containers. This scattered light effect is present in all types of fluorescence detection. Scattered light contributes to a significant portion of background noise, especially in biological samples, and it can be due to either Rayleigh, Raman, or Tyndall effects. These interferences can be best minimized by using fluorophores with relatively high Stokes shifts (typically >40–50 nm).

Fluorescence is more sensitive and selective than absorbance as a spectroscopic tool, not only because it is measured against a zero background but also because the magnitude of fluorescence signal, F, at low dye concentrations is expressed by Equation (1):

$$F = 2.303\Theta_f I_0 \varepsilon b C \quad (1)$$

where I_0 is the excitation power, ε is the molar absorptivity at the excitation wavelength, Θ_f is the quantum yield, b is pathlength, and C is the dye concentration. It can be seen that the limits of detection can be improved by a stronger excitation source. Laser-induced fluorescence (LIF) provides a superior approach to improve the sensitivity of fluorescence techniques. However, one must keep in mind that the limit of detection increases only as the inverse square root of excitation power and a strong excitation source can cause photo bleaching of the fluorophore. The limitations of conventional lasers as excitation sources include their high price, size, maintenance costs, and their limited wavelength selection. LIF in the NIR region (600–1100 nm) offers several advantages, and the recent advances in semiconductor laser technology have made the use of lasers more practical. In addition, the extensive use of NIR-emitting laser diodes in the telecommunications industry has made them more readily available. These types of lasers are inexpensive (typically <$150), small (~1 cm), and have a long operating lifetime (>100 000 h). A comparison of selected visible and NIR laser excitation sources is provided in Table 1. The gallium–aluminum–arsenide (GaAlAs) laser diode has drawn much interest because its emission wavelength of 785 nm is compatible with several classes of polymethine cyanine and naphthalocyanine (NPc) dyes that exhibit NIR fluorescence.[2]

Table 1 Comparison of NIR and visible laser excitation sources

Parameter	Laser diode	Argon laser
Wavelength (nm)	785	488
Lifespan (h)	100 000+	3000
Power output (W)	0.02	1–5
Power consumption (W)	0.15	1800
Replacement ($)	<150	>5000

In addition to the availability of diode lasers used for excitation, fluorescence detection in the NIR region has advantages since noise resulting from scatter is related to wavelength of detection by the factor of $1/\lambda^4$. Detection at 820 versus 500 nm results in more than a sixfold reduction in scatter noise. The low background interference in the NIR spectral region allows NIR fluorophores to be used as ideal probes in both biological and environmental applications. The advantages offered by the NIR region are summarized in Table 2. Detection in the NIR allows the commonly used photomultiplier tube (PMT) to be replaced with the more efficient photodiode and APD type. The APDs have excellent quantum efficiency in the NIR region. Table 3 illustrates the advantages offered by APDs in comparison with PMTs. These benefits include their low cost, compact structure, and their durability. In addition, they have low internal noise and very low power consumption. All these features allow NIR fluorescence

Table 2 Comparison of NIR and visible regions

Noise source	NIR region	Visible region
Detector	Low	High
Scatter (Rayleigh/Raman)	Reduced	6× greater at 520 nm than 820 nm
Background/auto-fluorescence	Mostly absent	Autofluorescence of biomolecules

Table 3 Comparison of APDs and PMTs

Parameter	APD	PMT
Replacement cost ($)	<50	~500
Lifetime (h)	>100 000	10 000, sensitive to overexposure
Quantum efficiency (at 820 nm) (%)	80	0.3
Internal amplification	High	Low
Size	Very small (nm)	Small (cm)
Power consumption	Very low	Low

instrumentation to be highly versatile and amenable to miniaturization. These features aid in the development of a portable compact and rugged instrument for field applications.

The recent progress in solid-state diode laser technology, the availability of commercial NIR absorbing dyes, and the development of diverse synthetic routes to functionalized NIR absorbing dyes have allowed NIR spectroscopy to be used in many diverse applications. These specific uses rely on the response of the chromophore after its excitation by NIR radiation. A simple absorber can be used in spectrophotometric analysis,[3] as molecular probes in immunoassays (IAs), or in applications of security printing, such as laser-readable bar codes.[4] The absorber can re-emit the input energy via fluorescence or phosphorescence. Also, the NIR-absorbing chromophore can convert the excited-state energy into other forms that can be utilized for specific applications. After absorption of laser energy, the chromophore can produce a local heating effect in the medium in which it resides.[3,4] This technique is used in the optical data recording technologies, such as WORM (write once read many) and DRAW (direct read after writing),[4] full color laser imaging, and in medicinal uses such as tissue welding.[3] Conversion of the NIR radiation into electrical energy by the chromophore is the fundamental basis for photovoltaic cells and electrophotography, including laser printing.[3,4] Furthermore, transfer of the chromophore's excited-state energy to endogenous ground-state molecular oxygen is the foundation for the selective destruction of neoplastic tissues in photodynamic therapies.[4,5] In particular, the NIR region provides a convenient spectral range for photodynamic therapies and in vivo imaging owing to the multicentimeter penetration of biological tissues.[5] Taken together, these benefits make NIR analysis an operator-safe, nondestructive, sensitive, and versatile technique that is taking the place of conventional methods, such as radiolabeling. Moreover, dilute samples can be analyzed safely and relatively fast compared with other techniques. Several applications have been developed in the past decade utilizing the various advantages offered by this novel methodology ranging from DNA sequencing, pH and hydrophobicity determination, metal ion detection, antibody (Ab) labeling, HPLC, and high-performance CE.

2 NEAR-INFRARED CHROMOPHORES AND LIGHT ABSORPTION PROPERTIES

To take full advantage of the high-technology NIR instruments, new NIR chromophores with specific properties are required. The comprehension of the color–structure relationship of near-infrared dyes (NIRDs) can provide useful information for their development since the light-absorption property of an organic molecule is correlated with its structural features. A highly conjugated system in either a linear or a cyclic arrangement in the molecule is responsible for the absorption maxima in the NIR region.

In principle, the absorption property of a chromophore is the characteristic of the energy that is absorbed to cause the electronic transition. NIR-absorbing chromophores require relatively low energy for the transition, and this corresponds to the longer wavelength of the electromagnetic spectrum in comparison with UV/VIS absorption. Since the transition energy is the energy required for a single electron to be excited from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO), the closeness between the HOMO and LUMO orbital is primarily responsible for the amount of energy required to induce this electronic transition. Therefore, the shift of the absorption maxima (λ_{max}) into the NIR region can be induced if the gap between the HOMO and the LUMO orbitals is brought close enough to give the transition energy in the range 48–26 kcal mol^{-1}. In practice, effective structural modification of the chromophore can cause the desired bathochromic shift. Griffiths summarized in detail the general strategies to develop new NIR-absorbing dyes using this approach.[3] These strategies include (i) extending the conjugation of a chromophore, (ii) increasing the interaction between electron donor and acceptor groups within a chromophore, (iii) altering the electronegativity of atoms within a chromophore, (iv) introducing specific branching or bridging within a chromophore, (v) metal complexation with a chromophore, (vi) intermolecular charge-transfer complex formation, and (vii) formation of a free radical that is part of the chromophore.

The Pariser–Parr–Pople molecular orbital (PPPMO) method[6] and XNDO/S method[7] are useful in the estimation of the absorption position of the chromophore that needs to be constructed. The perturbational molecular orbital (PMO) theory in the form of Dewar's rule

(1)

(2)

R = H, λ_{max} = 758 nm
R = CN, λ_{max} = 860 nm ($\Delta\lambda$ = 102 nm)
R = OMe, λ_{max} = 730 nm ($\Delta\lambda$ = –28 nm)

can also aid in the prediction of the light-absorption properties of chromophores with structural changes.[8] This rule is particularly useful in the development of new NIRDs since one can correlate the spectroscopic effects with a structural change at a specific position. In the basic analysis of an odd-alternate system of the conjugated chromophore, each alternate atom starting from a terminal donor is starred, as exemplified in **(1)**. Dewar's rule implies that an increase in the electronegativity at a starred carbon results in a hypsochromic shift. On the other hand, a bathochromic shift will be induced if the electronegativity of an atom at unstarred position is increased. In particular, a bathochromic shift of a cyanine chromophore is induced if the electron donor groups at starred positions or electron-withdrawing groups at unstarred positions are introduced.[6] This is further illustrated by the studies of substituted trimethine cyanines **(1)** on the basis of the PPPMO theory by Yasui et al., which showed the decrease in the electron densities at the starred positions and increase at the unstarred positions of the polymethine chain accompanying the first excitation of **(1)**.[9] An additional example of the application of Dewar's rule is given in **(2)** for three heptamethine cyanine dyes of a general structure **(2)**. As can be seen, the electron-withdrawing substituent (CN) at the central unstarred position of the chromophore causes a bathochromic shift and a hypsochromic shift is observed for the electron-donating group (OMe) relative to absorption of the parent unsubstituted dye R = H).[10]

3 CHEMISTRY OF NEAR-INFRARED DYES

So far, the theoretical correlation between structure and absorption properties has been discussed. These general rules can also be applied in the practical synthetic design of NIR-absorbing dyes. However, it should be noted that not only the light absorption properties of NIR chromophores but also other characteristics for different analytical applications are desired in the design of these systems. NIR chromophores with proper functional groups, organic and/or water solubility, high molar absorptivity or fluorescence maximum in the NIR region are required for most applications, including medical and optical purposes, dye lasers, and photographic sensitizers. These characteristics can be generally introduced in two ways, namely (i) by the structural modification of commercially available dyes and (ii) by direct synthesis utilizing appropriate precursors. Several examples of direct synthetic routes to NIRDs with specific applications are discussed below.

3.1 Indocarbocyanine Dyes

Functionalized NIR absorbing chromophores are widely used for labeling purposes. However, the commercial availability of such systems is somewhat limited. The first NIR-absorbing dyes containing $-N{=}C{=}S$ and $-C(O)CH_2I$ functionalities for selective coupling with amino and thiol groups, respectively, of biomolecules were synthesized by Waggoner's group.[11] These dyes, synthesized by using classical chemistry, contained the reactive group at one of the terminal heterocyclic units, and were extremely difficult to purify. Subsequently, Strekowski et al.[12,13] discovered a facile functionalization of indolium heptamethine cyanine dyes at the central *meso* position of the chromophore, and the synthesis of **(8a–c)** is given in Scheme 1 as an example. These dyes are substituted with an isothiocyanato or *N*-succinimidyl ester function for selective labeling at the amino group of proteins or bioconjugates such as amino-functionalized nucleotides.[13,14] The structural design of **(8)** includes the presence of sulfonic acid groups for excellent solubility in water and the overall symmetry of the molecule to contribute to the facile purification of the dye by simple crystallization. The symmetry is responsible for a high molar absorptivity of the chromophore. An important structural feature is the rigid trimethylene bridge in the center of the molecule that enhances the fluorescence quantum yield by decreasing conformational freedom of the NIR fluorophore in comparison with that of the fluorophore without the bridge.

The key synthetic step to **(8)** is a facile nucleophilic displacement of the chloro substituent in the intermediate product **(7)** which, apparently, involves an $S_{NR}1$ pathway.[12] In the preparation of **(7)** the starting material **(6)** is derived from dialdehyde **(11)** (for structure, see Scheme 2) by the reaction with aniline. The second component **(5)** is prepared efficiently by the reaction of **(3)** and **(4)**, as shown in Scheme 1.

This approach, as discussed above, was utilized by Flanagan et al.[15] in DNA sequencing involving capillary

Scheme 1 Synthetic route to heptamethine dyes. (i) Reflux in 1,2-dichlorobenzene. (ii) Reflux in EtOH in the presence of sodium acetate. (iii) Substituted sodium phenolate or thiophenol in DMF, 23 °C. [Strekowski et al.[13] approach.]

c H, Cl	**g** H, H
d H, F	

gel electrophoresis (CGE). Their dyes **(9a–g)** contain different atoms incorporated in the periphery of the chromophore, and have been prepared by substitution of the *meso*-chlorine atom in the intermediate dye with 2,5-disubstituted phenolates. The introduction of fluorine or heavy atoms such as iodine, bromine, and chlorine into the molecular framework has been found to affect the fluorescence lifetime without affecting the spectral properties of the chromophore. It was reasoned that introduction of heavy atoms induces spin–orbit coupling. As a result, the intersystem crossing (ISC) rates are enhanced producing a reduction in the excited-state lifetimes associated with the singlet state.

Recently, several commercial NIR-absorbing cyanine dyes have also been made available with amine-reactive groups for covalent coupling with synthetically altered nucleotides or oligonucleotides. The dyes are available under the Cy™ and IRD™ trade names, and have been synthesized by Mujumdar et al.[16] and LI-COR, Inc.,[17] respectively. The LI-COR IRD™ dyes, such as the nonsymmetric heptamethine dye IRD800™ phosphoramidite [**(18)**, Scheme 2], can be prepared by using the methodology described by Narayanan et al.[18] The synthetic route involves heating the bisaldehyde **(11)** and the hydroxy-functionalized quatenary indolium salt **(10)** with azeotropic removal of water (Scheme 2) to give the intermediate 'half' cyanine carboxaldehyde **(12)**. This intermediate generated in situ is further allowed to react with indolium alkyl sulfonate **(5)**, which furnishes the cyanine dye **(13)**. The absorption maximum of the NIR chromophore in **(13)** can then be fine tuned by addition of an electron-donating or electron-withdrawing group at the *meso*-position, as already discussed. Thus, the reaction of **(13)** with sodium phenolate **(14)** furnishes a phenoxy derivative **(15)**. Further treatment of the *meso*-substituted cyanine dye **(15)** with 1*H*-tetrazole **(16)** and 2-cyanoethyl tetraisopropylphosphorodiamidite

Scheme 2 Synthetic route to IRD800™ phosphoramidite. (i) Reflux in a mixture of benzene and *n*-butanol with azeotropic removal of water. (ii) Stirring in DMF at 23 °C.

(17) produces the final dye **(18)** (IRD800™) that contains a reactive phosphoramidite functionality for automated DNA synthesis applications. The spectral properties of IRD800™ are retained after coupling with the oligonucleotide. The unlabeled chromophore **(18)** exhibits an absorption maximum at 787 nm in methanol with a 25-nm Stokes shift in fluorescence and a 15.0% quantum yield, while the oligonucleotide-labeled chromophore **(18)** has an absorption maximum at 796 nm in water with a 23-nm Stokes shift and a 14.7% fluorescence quantum yield.

Using similar synthetic strategies, nonsymmetric pentamethine cyanine dyes have been developed by Mujumdar et al.[16] The dyes, such as Cy5-dUTP™ **(19)**, can be covalently linked to biomolecules including nucleotides and the conjugates used in enzymatic polymerization

processes. The dye-labeled dUTP analogs can be incorporated into DNA probes by nick translation, random priming, and polymerase chain reaction (PCR).

(19)

Cy5-dUTP™

3.2 Squarylium Dyes

In addition to the indocarbocyanine dyes, synthetic routes to indolenine–squaraine dyes, such as the *N*-succinimidyl ester derivative **(23)** (Scheme 3) for conjugation to proteins, are being developed. The squarylium dyes exhibit high photostability and quite long fluorescent lifetimes (nanosecond range) in aqueous solutions. Further benefits of using NIR-absorbing squaraine dyes for biological applications include the fact that their spectral properties (absorbance, emission, and lifetime) are independent of pH under physiological conditions (pH 6–9).[19] As shown in Scheme 3, Terpetschnig et al.[19] synthesized a water-soluble NIR-absorbing dye containing an activated ester moiety. The reaction of **(20)** and **(21)**[20] produced carboxy-substituted dye **(22)**. Following purification by preparative thin-layer chromatography (TLC), the nonsymmetric squaraine **(22)** was coupled to *N*-hydroxysuccinimide to produce the active ester **(23)**.

3.3 Phthalocyanines and Naphthalocyanines

The NIR-absorbing dyes such as Pc and NPc type are used as industrial colorants and in special applications of electronics and optics.[21] They efficiently complex various metal ions, and approximately 70 central metal ion species of Pcs are known. The cation is held in the planar 18-electron cavity and the metal cation can strongly influence the physical and spectral properties of the dye, including absorbance, emission, and fluorescence lifetime.[21] These NIRDs are sensitive to environmental changes such as pH and metal concentration. Classical synthetic routes to metal ion-containing Pc dyes [metal ion phthalocyanine (MPc) dyes] are illustrated in Scheme 4 where the metal ion acts as a central template for cyclotetramerization. As can be seen, MPc **(28)** is obtained directly from diiminoisoindolenine **(24)**, phthalic anhydride **(25)**, phthalonitrile **(26)**, or phthalimide **(27)** in the presence of a metal salt.[21] These dyes, though highly insoluble, are extremely stable and can be obtained by precipitation and further purified by sublimation. Metal ion-containing

Scheme 4 Classical synthetic routes to metal ion NPcs. (i) Heat in a high-boiling solvent (e.g. quinoline) with metal salt. (ii) Heat in a high-boiling solvent with urea and metal salt.

NPcs, such as **(31)** in Scheme 5, are obtained in a similar fashion.

The inherent sensitivity to metal and hydrogen ion concentration makes Pcs and NPcs ideal candidates for use in pH or metal determination. However, the poor aqueous solubility is a shortcoming that has to be overcome by structural modification or functionalization. One approach to overcome the insolubility is to incorporate sulfonate groups into the periphery of the existing Pcs or NPcs (Scheme 5). Patonay et al. at Georgia State University[22] have synthesized a tetrasulfonylated aluminum NPc **(31)** that can be incorporated into an optical probe for NIR metal determinations. Once incorporated into the fiber, the four sulfonate groups at the periphery of the NIR fluorophore interact with metal ions, such as K^+, to produce spectral changes in their absorption maximum (λ_{max}) and/or fluorescence intensity. The NIR probe studied by Patonay et al. provides metal detection over the range 1×10^{-8}–0.5×10^{-1} M.

4 ANALYTICAL APPLICATIONS OF NEAR-INFRARED FLUORESCENCE

LIF offers tremendous advantages over conventional analytical methods. The NIR region which has no background interference when coupled with LIF can attain sensitivities obtained by radiolabeling. This method also provides a step towards the maximum achievable sensitivity, that is, single-molecule detection. Many reviews of NIR fluorescence that describe dyes, instrumentation, and applications are available. An authoritative review, though dated, is provided by Warner et al.[23] A recent book summarizing the results of a North Atlantic Treaty Organization (NATO) Advanced Research Workshop covers the synthesis, optical properties and applications of selected NIRDs in high-technology fields.[24] In the next section, representative examples are reviewed to emphasize and acknowledge further the advantages and usefulness of NIR fluorescence techniques.

Scheme 5 Synthesis of tetrasulfonylated aluminum NPcs. (i) Reflux in 1,2-dichlorobenzene containing 1 M $AlCl_3$. (ii) Heat in oleum (15% of free SO_3).[22]

4.1 Applications of Non-covalent Labeling with Near-infrared Dyes

The NIRDs used as reporter molecules can be attached to the biomolecule of interest by two methods, via (i) covalent bond and (ii) noncovalent hydrophobic and/or ionic interactions. Theoretically, the hydrophobic backbone of many NIRDs allows for noncovalent labeling of large biomolecules. However, only a limited number of practical applications have been tested.

(34)

(35)

X = OPh-4(NCS), SPh-4(NCS); R_1 = Et, $(CH_3)_4SO_3Na$; R_2 = Et, $(CH_3)_4SO_3^-$

One of the earliest applications studied was the binding of indocyanine green (ICG) **(32)** to serum albumins by Kamisaka et al. in 1974.[25] Similar studies by Sauda et al.[26] using semiconductor laser fluorimetry illustrated that human serum albumin labeled with ICG provided picomolar detection limits. A comparison of noncovalent [**(33)** and **(34)**] and covalent dyes **(35)** labeling used in HPLC determination was investigated by Williams et al.[27] in terms of stability and specificity. Their results indicated that noncovalent labeling occurs rapidly at a physiological pH range. However, this interaction was found to be nonspecific and less stable than covalent binding.

4.2 Bioanalytical Applications of Covalent Labeling with Near-infrared Dyes

Many bioanalytical applications which rely on covalent labeling have been developed. Techniques that utilize this methodology include IAs, CE, DNA sequencing, and the development of gene probes.[28] This section details some of these applications with their associated merits and disadvantages.

4.2.1 Application of Near-infrared Fluorescence in Capillary Electrophoresis

Analytical separations of intact proteins using HPLC and CE have been shown to have excellent resolving power.[29] CE is particularly advantageous for protein analysis because of its higher chromatographic efficiency, faster separations time, and ability to use small amounts of material. The low molecular diffusion rates of proteins help achieve theoretical plate numbers as high as 10^6.

Many excellent reference books on CE have appeared in recent years,[30–32] and the reader is encouraged to refer to them for additional information not covered below. The *Handbook of CE*[31] is very thorough, while the CE primer series offered by Beckman Instruments[30] provides a brief overview of the principles of different separation techniques for a variety of applications.

Five main modes of electrophoresis have been developed over the years. These include capillary zone electrophoresis (CZE), isoelectric focusing (IEF), CGE, isotachophoresis (ITP), and micellar electrokinetic chromatography (MEKC). These different modes account for the wide applicability of CE to different analytes. However, one of the challenges in CE applications is the detection of analytes at low concentrations. This is a result of the physical dimensions of the capillary used for separation. Typical injection volumes in the nanoliter range combined with small detector windows of approximately 100–200 mm require highly sensitive detection systems.

UV/VIS absorbance is the most commonly used detection method for CE. The advantage is simplicity, low cost, and ease of use. Detection limits are in the range of 10^{-13}–10^{-16} mol for direct absorption (a factor of 10 less for indirect methods). Other methods employed include MS, electrochemical, refractive index and radiometric detection.[28] Fluorescence detection can greatly enhance the sensitivity of CE methods. For example, direct fluorescence provides detection limits in the range of

10^{-15}–10^{-17} mol (a factor of 10 less for indirect methods). However, the number of compounds that fluoresce naturally is limited and derivatization of analytes with a fluorescent tag is frequently required. Fluorescence emission is measured against a zero background signal, resulting in improved detection limits in comparison with absorption methods. Furthermore, LIF coupled to CE provides a sensitivity of approximately 10^{-18}–10^{-23} mol. This improved sensitivity of fluorescence detection is attributed to concentrating high power monochromatic light into a very small area, which provides an ideal excitation source for CE fluorescence detection.

LIF is one of the most sensitive methods of detection available for use with CE. Although the number of publications on the subject has been rising steadily each year, the practical use of LIF with CE has been limited owing to scatter from incident light reflected by the capillary walls with on-column LIF detection. Scatter can be greatly reduced by utilizing postcolumn detection using a sheath-flow arrangement, first described by Chen and Dovichi.[33] However, this set-up adds a significant amount of complexity to the method, requires additional equipment such as a low-flow HPLC pump, and is not commercially available. Another deterrent is the high cost associated with visible lasers which are suitable for excitation of the more popular fluorescent labels including fluorescein isothiocyanate (FITC) and 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde (CBQCA).

Several authors have reported on the advantages of using semiconductor lasers with CE. Most investigations to date have involved the use of far-red fluorescent dyes. Williams et al.[34] described a diode laser-based indirect absorbance detector for the analysis of a series of tetraalkylammonium ions. In this study, rhodamine 700 ($\lambda_{abs} = 642$ nm, $\lambda_{em} = 668$ nm) was used as a background absorber, and detection limits were found to be of the order of 20 mM. Another study utilizing a time-resolved photon counting fluorimetry CE method was described by Song et al.[35] Four fluorescent dyes were evaluated using an LIF detector with a 74-ps pulsed semiconductor laser emitting at 655 nm. The dyes investigated included methylene blue ($\lambda_{abs} = 665$ nm, $\lambda_{em} = 685$ nm), oxazine 725 ($\lambda_{abs} = 655$ nm, $\lambda_{em} = 679$ nm), 1,1′,3,3,3′,3′-hexamethyl dicarbocyanine (HIDC) iodide ($\lambda_{abs} = 636$ nm, $\lambda_{em} = 667$ nm), and rhodamine 700. The lowest limit of detection was reported to be 2 fmol, which was obtained for oxazine 725 at a concentration of 0.2×10^{-5} M. Fuchagami et al. synthesized a novel far-red fluorescent labeling dye for use with a semiconductor LIF detector.[36] Several amino acids were derivatized with 9-cyano-*N*,*N*,*N*′-triethyl-*N*′-(5′-succinimidyloxycarbonylpentyl)pyronine chloride ($\lambda_{abs} = 663$ nm, $\lambda_{em} = 685$ nm) and were separated and detected by CE. The experimental system used a 2-mW semiconductor laser emitting at 660 nm and a PMT detector. Detection was performed off-column using a sheath flow cell to reduce Rayleigh scatter, achieving a limit of detection [signal-to-noise ratio (SNR) = 2] of 800 zmol.

Table 4 Comparison of visible (R6G) and NIR (IR132) single-molecule detection. [Adapted from Soper et al.[38]]

Parameter	Visible	NIR
Excitation wavelength (nm)	532	800
Observed wavelength (nm)	570	840
Instrument response (fwhm) (ps)	100	250
Photon detection efficiency	0.0007	0.007
Probe volume (pL)	1.1	0.8
Transit time, τ_t (ms)	24	10
Background rate in time window (counts s^{-1})	225	145 (±12)
Average photons/molecule	39	18 (±4)
Detection efficiency (%)	78	97 (±7)
Probability of error	0.3	0.04

The advantages of using APD CE detectors at wavelengths above 650 nm have been reported. Kawazumi et al.[37] compared PMT and APD detection using oxazine 725 excited by a 29-mW semiconductor laser emitting at 655 nm. The APD was operated in a near-Geiger mode with time-gated detection, resulting in a 47-amol limit of detection. The APD limit of detection was 98 times greater than that with a PMT. As already mentioned, detection in the NIR region offers considerable advantages over working in the conventional UV/VIS region.

A significant amount of work with NIR fluorescent dyes including their applications to CE has been conducted at Louisiana State University by Soper et al.[38–40] They observed bursts of photons from single NIR fluorescent molecules in a flowing stream using a Ti : sapphire laser (12 mW) and an APD detector. The dye infrared (IR)-132 ($\lambda_{abs} = 805$ nm, $\lambda_{em} = 847$ nm) at a concentration of 25 fM in methanol was used in these experiments with time-gated off-column detection.[38] A comparison of a single-molecule detection of visible (R6G) dye and the NIRD IR-132 (Table 4) shows a significant reduction in background fluorescence, resulting in a lower discriminator threshold and error probability, and thereby provided a higher single-molecule detection efficiency in the latter case. A set-up similar to the photon burst experiment, using continuous excitation and CE with on-column detection, was utilized for an investigation of binary solvent effects in CZE with several NIRDs and dye-labeled amino acids.[39] One of the dyes substituted with an isothiocyanate group **(37)**, was synthesized from dye **(36)** by Soper et al. and covalently bound to amino acids. The results showed that the detectability, efficiency, and resolution of the

NIR methodology can be significantly improved with the use of mixed organic–aqueous running buffers (Table 5). However, cationic NIRDs were found to be problematic at low concentrations owing to capillary wall adsorption. The on-column limit of detection was found to be 0.4 zmol using the dye HDITCP ($\lambda_{abs} = 780$ nm, $\lambda_{em} = 825$ nm) at a concentration of 2×10^{-10} M in 95% methanol, and the limit of detection of a dye-labeled amino acid was 21 zmol, using a 1×10^{-9} M solution in 9:1 methanol–water buffer. A comparable CE system with a 10-mW Ti:sapphire laser emitting at 795 nm was used to evaluate NIR fluorescence detection for CGE and DNA sequencing applications. A comparison between detection for NIRD-labeled primer **(38)** and fluorescein labeled primer **(39)** is shown in Table 6. Under similar conditions, the significantly lower Raman contributions and background fluorescence resulted in a background of 10 000 counts for NIR compared with >200 000 counts for visible excitation in contrast to the larger detection efficiency at 800 nm in comparison with 550 nm. Although the NIRD exhibits a lower quantum efficiency, a much lower limit of detection of 34 zmol was achieved for an IRD41™ labeled M13 primer ($\lambda_{abs} = 786$ nm, $\lambda_{em} = 812$ nm) in comparison with 1.5 amol for the visible primer primarily owing to the significantly smaller background in the NIR region.[40]

Until recently, all near-infrared laser-induced fluorescence (NIRLIF) work completed to date involved the use of laboratory-made CE systems and detectors. However, two commercial LIF detectors are currently available for use with CE, manufactured by Beckman and Zeta Technology. The Beckman LIF detector is specifically designed for use with their P/ACE™ CE instrument, while the Zeta LIF detector is a general-purpose detector also applicable to HPLC use. Both detectors are optimized for use in the visible region and utilize PMT detectors, with laser excitation via a fiber-optic cable. Recently, Patonay et al. at Georgia State University, actively involved in research in other areas of NIR fluorescence, developed a simple interface between a commercial APD-based NIR-LIF detector and a CE instrument. The system retained the fully automated injection, separation, and data collection capabilities of the commercial CE instrument and was optimized for detection around 820 nm with laser excitation at 787 nm, where the detector sensitivity was improved about 400-fold in comparison with the conventional PMT-based LIF detector.

To illustrate the challenges in design of developing a NIR fluorescence detector interface to exploit fully the advantages offered by this region, a more detailed description of the work done by Baars et al.[28] is presented in the following section. A Beckman LIF detector with the P/ACE™ 5000 CE instrument was modified to accommodate the diode laser excitation and NIR fluorescence detector. The back mounting plate and a portion of the self-aligning beam probe assembly of the Beckman LIF detector was used in the interface. The flat mirror, filter holder, PMT and detector electronics were removed resulting in a collimated fluorescence output from the LIF cartridge, passing through the beam block and beam probe, to allow interfacing with the NIR detector. A proprietary microscope and laser assembly manufactured by LI-COR, Inc. (Lincoln, NE, USA) was used as the NIRLIF detector. This detector system is comparable to components used in the commercially available automated DNA sequencing instrument[41] (LI-COR Model 4000), with the exception of modified focal length optics and an extra band-pass filter. The laser assembly for excitation contained a GaAlAs laser diode emitting around 787 nm (20 mW peak power, modulated with a 50% duty cycle) and a focusing lens (focal length $f = 46$ mm). The detector consisted of a three-stage Peltier-cooled APD. The detector assembly contained a plano-convex lens ($f = 31$ mm) to collect the fluorescence image, three identical band-pass filters (825 ± 15 nm)

(38)

(39)

to reduce background noise from laser scattered light (Rayleigh), and a second plano-convex lens ($f = 31$ mm) to refocus the signal on to the APD photoactive area (0.5 mm diameter). The interface between the LIF cartridge and the NIR fluorescence detector comprised an aspheric condenser lens mounted immediately past the beam probe assembly. An 800-μm circular aperture was installed at the focal point of the condenser lens to reduce stray light. The NIR detector was fixed to an $x-y-z$ micrometer stage installed on the mounting plate and focused on the image produced by the interface lens. The diode laser was disconnected from the LI-COR microscope assembly and was mounted on another $x-y-z$ micrometer stage mounted on the side of the CE base. The laser signal was focused directly on the excitation fiber, resulting in a 4 mW average excitation power at the capillary interface. The optical path of the complete system is shown in Figure 2.[28]

Fluorescence emission was collected by the mirror and reflected as a collimated beam at 180° from the angle of excitation and the collimated beam was then focused by the aspheric condenser lens to the appropriate image size, at the focal length of the detector. The detector optics filter the fluorescence signal through three band-pass filters prior to focusing the signal on the window of the APD detector. Instrument control and data collection of the P/ACE™ 5000 CE system were fully automated through the Beckman System Gold chromatographic software (version 8.01), run on a 486-33 personal computer. The detector signal was interfaced with the chromatographic software. This was accomplished by connecting the analog detector output to a Beckman 406 analog-to-digital convertor (ADC), whose output can be collected by the chromatographic software. In their set-up, the P/ACE™ 5000 CE unit was used to control all CE functions such as capillary rinses and injection and separation parameters and in addition, it was

used for data collection and chromatographic integration, reporting, and plotting functions. The maximum detector output was matched to the 2-V input limit of the ADC using a simple voltage divider circuit. A block diagram of the main instrument components is shown in Figure 3.

The image size produced by the aspheric condenser lens was evaluated for proper matching of the image size to the photodiode active surface area. The experimentally determined mean diameter is 0.575 mm, indicated a slight overfilling of the 0.5-mm detector window. The rapid change in signal upon minor detector position was a good indication of an acceptable image size match. A three-dimensional representation of the image produced by the aspheric condenser lens is shown in Figure 4.

The sensitivity of the system was evaluated by injecting serial dilutions of the labeling dye NN382 **(40)**, (λ_{abs} = 776 nm, λ_{em} = 796 nm, H_2O) which is suitable for use with the systems excitation and detection wavelengths (Figure 5). A linear detector response ($r = 0.9999$) was observed over more than a 250-fold concentration range between 1.4×10^{-9} and 5.5×10^{-12} M (Figure 6). A SNR, signal/root mean square noise) of 15 was observed for a 70-nL injection of the 5.5×10^{-12} M solution, which indicated a limit of detection (SNR = 3) of approximately 80 zmol. The electropherogram of a 70-nL injection of the 5.5 pM solution (385 zmol injected) is provided in Figure 7.

Figure 3 Experimental instrument component diagram.

The sensitivities obtained were under 100% aqueous conditions, and additional improvements could be expected with the use of organic modifiers, cyclodextrins, or micellar additives above their critical micelle concentration in the run buffer, from an improved fluorescence quantum yield when the dye is exposed to a more hydrophobic environment. Comparison of the photophysical properties of the dye in methanol suggested that a fourfold improvement in signal could be obtained when using the dye NN382 in a more hydrophobic run buffer, containing a cosolvent such as methanol. Additional improvements in detection sensitivity could be attained using an NIRD with an emission wavelength better matched to the band-pass filters in the detector. The current system utilizes three 825-nm band-pass filters that significantly attenuate the fluorescence signal emitted at 800 nm. The relative fluorescence signal reaching the detector is only a fraction of the fluorescence produced.

Light collection efficiency and lens and filter transmission efficiency influence the amount of light that will

Figure 4 Three-dimensional representation of the image produced by the aspheric condenser lens.

(40)

Figure 5 Absorbance and fluorescence spectra of NN382 (in phosphate buffer, pH 7.2).

actually reach the detector. Thus, the maximum efficiency of the optical path in the experimental set-up can be estimated as follows:

- light collection efficiency of mirror: 10%;
- transmission efficiency of aspheric condenser lens: 98%;
- transmission efficiency of first detector lens: 98%;
- maximum transmission efficiency of each band-pass filter: 70%;
- transmission efficiency of second detector lens: 98%.

The overall result is that only about 3.2% of the fluorescence signal reaches the detector.

The quantum efficiency of the detector (even though relatively high for an APD at 800 nm, ~80%) further reduces the number of photons that actually produce a detector response. The improvement that can be attained when better matching band-pass filters with the dye emission profile, or dye selection with the system band-pass filters, can be estimated. A comparison made between the area of the NN382 **(40)** emission curve from 810 to 840 nm and the maximum area that could be attained from 781 to 811 nm (±15 nm from the emission maximum) shows that maximum area was 70% larger than the area of the curve corresponding to the band-pass filter wavelengths. Using a dye with an emission wavelength

Figure 6 NN382 response curve (384–98 zmol on-column).

Figure 7 Electropherogram of 70-nL injection of 5.5×10^{-12} M NN382.

around 825 nm could therefore result in about a 1.7-fold increase in signal, assuming a comparable fluorescence emission profile. The noise would remain unchanged, suggesting that an additional 1.7-fold improvement in SNR could be attained. All the above-mentioned factors demonstrate important aspects of LIF instrumentation design. To optimize sensitivity, laser excitation should occur below the absorption maximum when a dye has a relatively short Stokes shift. Band-pass filters should be optimized for the fluorescence emission maximum of the dye. This design will effectively attenuate the Rayleigh scatter from the laser while optimizing fluorescence signal collection.

The automated NIRLIF system developed has sensitivity in line with state of the art results obtained by several investigators utilizing highly optimized laboratory-made detection systems. The latter systems utilize high-quality microscope optics for fluorescence emission collection and tightly focused laser excitation beams. Few investigators have reported limits of detection below the zeptomole range. Sub zeptomole detection limits have been achieved using CE by investigators including Soper et al.[38] (0.4 zmol) and Dovichi et al.[33] (0.050 zmol). Impressive sensitivities as low as single-molecule detection have also been reported for molecules in a flowing stream, demonstrating the possibilities of LIF when used with CE.[42,43] In order to attain these sub zeptomole levels, an off-column sheath-flow detection arrangement was generally utilized to reduce the amount of background scatter. Neat dye solutions were used under conditions that optimized the quantum yield of the dye (Φ), not necessarily desirable for real CE applications. High laser powers, time gating and data smoothing have also been utilized to achieve these results.

The data presented here are for an NIR labeling dye used under 100% aqueous conditions in a fully automated instrument, suitable for routine use. Additional improvements in sensitivity could be achieved by increasing laser excitation power, improving the dye fluorescence quantum yield, and optimizing the dye emission profile with the band-pass filters. The NIRLIF system uses more compact, rugged, and less expensive components with an expected lifetime of >100 000 h. The fully automated injection, separation, and data collection capabilities of the commercial CE system were preserved.[28]

The fully automated system developed was then used to evaluate the suitability of the NIRD NN382 **(40)** as a peptide labeling agent. Six angiotensin-I (Ang-I) variants were selected as model peptides for derivatization and separation studies.[44] The calculated charge-to-mass ratios of the derivatives and excess dye (at pH 7.2) are given in Table 7, listed in expected order of elution in a normal polarity CZE separation. The smallest charge-to-mass ratio difference is between the human and Val-5 forms, where the substitution of valine for isoleucine

Table 7 Sequence of labeled Ang-I peptides listed in order of decreasing charge to mass ratio and expected elution order in a normal polarity CZE system (amino acid differences from the human form are bold and underlined)

represents a difference of a single methyl group for the 2295 (formula weight) labeled peptide.

The closely related decapeptides were labeled with the NIRD, separated using CE, and detected by NIRLIF. Derivatization of the peptides was achieved under aqueous conditions using 2.5–500 pmol of Ang-I in a 50-μL sample (5×10^{-8}–1×10^{-5} M). The fluorescence response was linear over a 200-fold range ($r > 0.9986$) and the SNR of a 1.3-amol injection of the Ang-I variants was >15, indicating a limit of detection (SNR = 3) of <240 zmol. Four of six peptides were resolved from each other and excess dye using CZE. Two pairs of co-eluting peptides were successfully resolved using MEKC. Two neutral NIRDs were identified as suitable markers for measuring electroosmotic and micellar flow.[44]

Another application evaluated with the NIRLIF system was in CGE. The suitability of NIRLIF detection with CGE was investigated. The purity of NIR-labeled primers was assessed, and detection linearity and sensitivity using CGE were evaluated. Slab gel electrophoresis has been used for many years for the analysis of proteins, oligonucleotides, DNA, and other biomolecules. The applications of this technique are very powerful and widespread, but also slow, labor intensive and prone to poor reproducibility.[45] CGE was developed to automate and simplify traditional gel electrophoresis methods. The advantages of using CGE include the ability to automate the process fully, provide on-line quantitative detection, and use smaller sample amounts.[30–32,45] The capillaries are superior at dissipating heat, allowing the use of higher voltages, resulting in improved efficiencies and shorter run times.

LIF detection has been successfully applied to DNA sequencing methods. Swerdlow et al.[46] reported sequencing rates of up to 1000 bases per hour using fluorescent-labeled primers. Another scheme uses fluorescent intercalating dyes, such as those marketed by Beckman, for the analysis of ds DNA with LIF detection. Although the total sample throughput is still limited using CE compared with slab gel methods, this limitation is likely to be overcome. Through the use of one-channel, four-dye detection schemes and the development of multicapillary instruments, this limitation can be overcome. Beckman has recently introduced an eight-capillary CE instrument for DNA analysis and Ueno and Yeung reported on the use of a 100 capillary bundle.[47]

CGE with LIF detection was utilized to assess the purity of NIR-labeled oligonucleotides. The CGE method showed great sensitivity, with limits of detection around 90 zmol and a 1000-fold linear dynamic range. The number of theoretical plates obtained for the primers exceeded 300 000. The excellent sensitivity and high separation efficiency observed for the NIR-labeled primers indicate their suitability for many other CGE applications.[28] Sensitivity results are comparable to those reported by Williams and Soper[40] for a similar NIR-labeled primer. The excellent sensitivity and separation efficiencies obtained for the NIR-labeled primers suggest they may be suitable for many of the other CGE applications described earlier.

The use of fluorescent-labeled primers in binding studies of synthetic oligonucleotides, such as antisense therapeutics, has been demonstrated. Vilenchik et al.[48] monitored the hybridization of a phosphorothioate target with a complementary labeled DNA probe. Protein to DNA binding studies were shown by Xian et al.[49] using a CE mobility shift assay with CGE. An assay to determine the activity of a transcription factor (SpP3A2), obtained from the nuclei of a single sea urchin egg, was based on the difference in mobility of a free or bound fluorescent labeled DNA probe.

4.2.2 Application of Near-infrared Fluorescence in Immunoassays

IA is a method of analysis that relies on specific interactions between an Ab and an antigen (Ag) to measure a variety of substances, ranging from complex viruses and microorganisms to simple pesticide molecules and industrial pollutants. To observe and measure this reaction, a label is introduced via a second Ab. Conventionally, this label consists of a radioactive isotope (radioimmunoasay (RIA)), an enzyme (enzyme-linked immunosorbent assay (ELISA)) or a fluorescent molecule (fluorescence immunoassay (FIA)). The use of Abs as analytical regents was first reported in 1959 when Berson and Yalow successfully demonstrated the measurement of picogram levels of human insulin in samples of body

fluids by RIA.[50] Since then, various IAs for detecting hundreds of molecules of endogenous and exogenous origin have been described. This technique proved to be reliable, fast, and very sensitive; many other RIAs have been developed for clinical and medical tests since then. The use of immunochemical techniques in the environmental field was first proposed in 1971 by Ercegovich,[51] who suggested the use of immunological screening methods for the rapid detection of pesticide residues and for confirming results of conventional analysis. An RIA for the insecticides aldrin and dieldrin was the first reported IA for an environmental contaminant.[52] Although a few RIAs still exist in the medical field, they are seldom used in environmental and food analysis because of the need for special handling and disposal of the radioactive materials. Radiolabels were gradually replaced with enzyme labels owing to the hazards associated with radioactive materials. ELISA, which was first introduced by Engvall and Perlman in 1971,[53] has become perhaps the most popular IA format used in laboratories today. The modern diagnosis of many diseases, especially infectious diseases, is almost completely dependent on these assays. In diseases of global importance such as acquired immunodeficiency syndrome (AIDS),[54] cysticercosis,[55] malaria,[56] filariasis, and schistosomiasis,[57,58] IAs play a key role in screening and diagnosis.

Utilizing the advantages of fluorescence over absorbance, conventional fluorophores can be theoretically capable of detecting fewer than 10^6 molecules L^{-1}[59] in conjugation with the highly specific activity provided by IAs. However, in practice, the high background from the biological samples autofluorescence, or sample reagents and scattering and quenching effects of solvents, limit the detection to about 10^{-10} molecules L^{-1}. LIF provides an alternative to improve the sensitivity of fluorescence in IAs. The use of LIF in IAs has been reviewed.[60–62] The limitations of conventional lasers as excitation sources are their high price, size, maintenance costs and their limited wavelength selection. LIF in the NIR region (600–1100 nm) offers several advantages. Recent advances in semiconductor laser technology have made the use of lasers more practical. The widespread use of NIR-emitting laser diodes in the telecommunications industry has made them more readily available. This type of laser is inexpensive (typically <$150) and small (~1 cm) and has a much longer operating lifetime (>100 000 h).[63]

The GaAlAs laser diode has drawn much interest because its emission wavelength of approximately 800 nm is compatible with several classes of polymethine cyanine dyes, which exhibit NIR fluorescence. Detection in the NIR region allows one to replace commonly used photodiodes by APD. The APDs have excellent quantum efficiency in the NIR region. Some of the advantages of APDs are that they are much cheaper, more compact, and longer lasting. In addition, they have low internal noise and very low power consumption. All these features make the NIR fluorescence IA highly amenable to miniaturization and can aid in the development of a portable, compact and rugged instrument for field application.

Heptamethine cyanine dyes are a class of NIR fluorophores that have been used for DNA sequencing, pH and hydrophobicity determination, metal ion detection, and Ab labeling.[63] They are ideal for labeling Abs involving conjugation chemistry, e.g. the reaction of the isothiocyanato group (NCS) on the NIRD with the primary amine groups on Abs. These dyes have high molar absorptivities (ca. 10^5 L mol^{-1} cm^{-1}), high quantum yields (20–40%), relatively short fluorescence lifetimes (500–1000 ps) and are small (~1000 Da). The small size of these dyes in comparison with the target molecule allows for a high number of labels per Ab without compromising Ag/Ab interactions. This implies higher selectivity and signal coupled with low background interference, in addition to the previously discussed advantages offered by the NIR region. Additionally, the use of a solid matrix generates a stronger signal by concentrating the fluorescent molecules and thereby reducing quenching effects of the solvent.[2]

Boyer et al. were the first to demonstrate the feasibility using diode laser detection in the NIR region.[64] They compared the efficacy of the NIR assay method with the conventional ELISA method. Williams[65] constructed an NIR fluorescence detector for detecting fluorescence in an IA format. The set-up developed is illustrated in Figure 8. The instrumentation comprised an excitation source coupled with a fiber-optic cable, a silicon photodiode as detector, a sample-holding apparatus that could be adapted to hold various forms of solid support matrices coupled with a motor drive, and a data acquisition interface. The instrument could detect concentrations of 100 pmol of NIRDs. Using this set-up, the near-infrared

Figure 8 Block diagram of NIR fluorescence detector.

fluorescence immunoassay (NIRFIA) on a nitrocellulose matrix was capable of detecting 5×10^{-10} M human immunoglobulin G (IgG). The overall assay could be performed in less than 2.5 h in the absence of the substrate development step which is employed in the conventional ELISA method. This NIRFIA allowed the detection of approximately 470 00 labeled Ab molecules.

This method developed, however, had its disadvantages. A high degree of scatter generated by the membrane, problems with nonspecific binding of the conjugate, and its lack of compatibility with the most common format of modern IAs, the microtiter plate assay format, limit its practical use. In continuation of the development of solid-phase NIRFIA, the abovementioned issues and others were addressed in a study by Swamy.[2] An NIRFIA was developed based on the heptamethine cyanine dye NN382 **(40)**. The dye used in this study had a high molar absorptivity ($\varepsilon = 180\,000\,\mathrm{L\,mol^{-1}\,cm^{-1}}$) and quantum yield ($\Phi = 0.59$, for dye–Ab conjugate). The isothiocyanate functionality reacts selectively with the amino group of the Abs to form a stable thiourea bond. The presence of the sulfonated groups makes the dye highly water soluble, making it ideal for labeling Abs. Another advantage of the negatively charged sulfonate groups on the dye is that it minimizes nonspecific binding to the solid matrix (polystyrene (PS)).

A solid-phase NIRFIA was systematically developed in the following steps. A LI-COR 4200 prototype fluorescence microscope[41] was coupled with an orthogonal scanner and was evaluated for optimum depth of view. Next, the optimum scanner operating conditions were determined in terms of gain, offset, and scan speeds to optimize settings for maximum dynamic range and SNR and ensure reproducible scans. Appropriate modifications to the mounting of the scanner microscope and scanning platform were made to allow the examination of microtiter plates (Figure 9). The linear response of the detector was verified with increasing gain for a given voltage setting. A number of microtiter plates (solid matrix) were then evaluated in order to provide the one with minimum background noise. Once the reader had been configured and the solid support had been augmented, the procedure for covalent conjugation of NIRD NN 382 **(40)** to goat antihuman immunoglobulin G (GAHG) was systematically optimized in terms of pH, temperature, time of reaction, and reactant molar ratio. The conditions that provided the maximum results were a pH of 10, an initial dye : Ab ratio of 1 : 125, a temperature of 25 °C and a coupling time of 1 h. These conditions are all critical parameters since any deviation results in under- or overlabeling of the Ab, which, in turn, results in a low specific activity and detection ability. The absolute concentration of reactants was found to be critical for the rate of the coupling reactions; therefore, in the optimization procedure, stock solutions of dye ($10\,\mathrm{mg\,mL^{-1}}$) and Ab ($1\text{–}3\,\mathrm{mg\,mL^{-1}}$) concentrations were used. Although the conditions for coupling other species of Ab were not optimized, other conjugates were successfully prepared with high specific activity. The optimum conjugation procedure was defined by the conditions that produced an NIRD-labeled Ab with the highest specific activity in an immunosorbent assay for normal human immunoglobulin G (NHIgG). The best conjugate was used to determine detection limits for the assay and was able to detect 2×10^{-11} M of NHIgG. This provided a sensitivity about 10 times greater than that achieved by conventional labels in similar assays. Finally, the assay was validated by 100% agreement with clinically diagnosed samples for schistosomiasis and its cross-reactors.[2]

Figure 9 Model assembly to scan microtiter plates.

One major disadvantage of this method is the lack of commercial instrumentation for the assay. Quantification of the signal obtained in an image format is problematic. However, commercial software for quantifying on line signals from DNA sequences in the NIR region is available (LI-COR). Adaptation of similar software for microtiter plate scans would be immensely helpful. The method developed does have many advantages over conventional methods and the versatile nature of the scan bed does not limit this assay to the microtiter format. Technically, the scanner could scan any matrix, limited only by the physical dimensions of the scanner (ca. 23 cm and 61 cm long). This could allow for scanning multiple assays and 500–1000-well plates. The assay is very quick, requiring less than 20 min for the assay itself, and requires fewer steps than ELISA. The ability to detect lower concentrations of Abs would help in earlier diagnosis and an opportunity to test drugs against opportunistic infectious agents at an earlier stage. The labeling of Abs with NIRDs provides an important advancement to IAs and the comparatively small size of the NIRD allows for a higher molar ratio of NIRD per Ab. This in turn yields a higher signal and allows for lower detection limits. The assay has also been validated for clinical samples and could be further evaluated in the development of a diagnostic test.

In principle, various bioanalytical methods can be developed using the NIR immunochemistry described in the preceding section. To demonstrate the versatility of the method, Swamy et al. developed two bioanalytical applications utilizing NIRFIA in collaboration with the State University of New York (SUNY) at Brooklyn and the Department of Entomology and Environment Toxicology at the University of California, Davis, CA, USA. The first application involved an NIR-labeled Ab in the detection of extracellular Ag expressed on cells. This demonstrated the feasibility of using NIR-labeled Abs in clinical imaging applications such as NIR optical tomography. The second application uses the NIRFIA as an analytical tool in environmental applications in the quantitative analysis of two pesticides, bromacil and fenvalerate.

In the evaluation of the NIRD-labeled Ab for imaging applications, the NIRD NN82 was coupled to monoclonal Ab E48 (MAb E48) and the conjugate was evaluated in a direct assay to detect a 22-kD Ag expressed on the surface of human squamous cell carcinoma line (HuSCC) A431. The specificity of binding was confirmed in a competitive assay. The preliminary results showed good sensitivity and specificity of the NIRD-labeled Ab. In the environmental application, the assay was evaluated in a rapid tracer format competitive assay for the detection of the pesticides bromacil and pyrethroid. In this assay, the specific Ab captured on the surface of microtiter plate well and the tracer with fluorescent label compete with the analyte for the Ab. The results obtained showed that the NIRFIA was at least as sensitive as ELISA, with both assays detecting pesticides in the micrograms per liter (parts per billion) range.[2]

The chemistry and the instrumentation of the NIRFIA technique for environmental applications have been developed, but are amenable to further miniaturization. Further optimizations would allow for the future construction of compact instrumentation for analysis which could conduct fast and reliable assays at remote locations. In continuation of this approach, preliminary results obtained in our laboratory demonstrated the feasibility of using the NIRFIA approach for an NIR/fiber optic immunosensor (FFOI). This approach is particularly useful for measuring small amounts of analyte and can be automated and carried out in remote locations. Several fluorescent immunosensors have been reported; however, lack of commercial instrumentation and labels limit the use of these techniques and most applications utilize UV/VIS dyes. The applications of the visible fluorescent immunosensors described are all susceptible to interference from biomolecules such as bilirubin and porphyrins. A comprehensive review of immunosensors has been published by Robinson et al.[66] Danesvar[67] developed a NIR/FFOI for detection of trace amounts of human IgG and *Legionella pneumophilia*. They optimized the assay on different solid phases such as poly(methyl methacrylate) (PMMA) and PS. The PS coating method eliminated the activation process required with PMMA, thereby reducing the preparation time by 18 h; in addition, it also eliminated the protein G step of the previous assay. The assay was carried out in a sandwich format (Figure 10). The set-up used to measure the signal (Figure 11) allowed concentrations of 10–11 M for IgG (SD = 0.13) and 0.5 ng mL^{-1} for *Legionella pneumophilia* sera type 1 (LPS1)[67] to be detected. These results were comparable to those attained by conventional ELISA. Another application using a similar format was developed by Evans[68] and provided a competitive assay for the pesticide bromacil. A detection limit of 5 ppb was obtained, which was slightly higher than that reported for ELISA (0.1 ppb). However, the method had advantages since it did not require extensive sample preparation, the assay time was substantially reduced, and the assay could be adapted for remote site analysis.[68]

The NIR/FFOI technique in principle is a flexible methodology, which can be theoretically adapted to develop assays for any compound for which Abs are available, including infectious agents, serum analytes, and environmental pollutants. This technique provides a real-time analysis with automated readout capabilities, eliminating the need for operator intervention or

Figure 10 Sandwich assay on fiber-optic probe.

Figure 11 Fiber-optic immunosensor set-up.

complicated sample preparation. Although the detection optics for the assay were originally constructed on a 2×3 ft optical table, the set-up can be reduced in size. The preliminary sensitivity, selectivity, and simplicity of the assay are encouraging and further design refinement and other applications should aid the development of versatile NIR/FFOI.

4.2.3 Application of Near-infrared Fluorescence in High-performance Liquid Chromatography

Another bioanalytical application developed using the advantages of NIR fluorescence is HPLC detectors. In recent years, the ability to measure ultralow levels of pharmaceuticals in biological matrices has presented significant challenges. Using fluorescence as a tool for detection, sensitivities of picograms per milliliter have been achieved. Rahavendran and Karnes have described the advantages of LIF detection in HPLC.[69] There have not been many publications dealing directly with HPLC detection in the NIR region. Until recently, two groups worked on the development of applications of NIR fluorescence in HPLC, Winefordner's group at the University of Florida and Ishibashi's group in Fukuoka, Japan.

One of the first NIR fluorescence-based HPLC detectors was developed by Ishibashi's group. They detected 0.3 pg of a carbocyanine dye,[70] with instrumentation comprising a 3-mW diode laser emitting at 780 nm with a PMT cooled to $-20\,^{\circ}$C for detection. They reported a detection limit of 1.9 pg at room temperature. Sternberg et al.[71] of Beckman Instruments used a 2.5-mW diode laser coupled with a commercial diode-array detector and achieved a detection limit of approximately 10^{-10} M for a carboxyl cyanine-labeled oligonucleotide. Winefordner et al. explored the detection of cyanine dyes in different instrumental configurations,[72] using a diode laser for excitation with a PMT for detection. They achieved detection of 46 000 molecules in a liquid jet fluorescence spectrometer. Karnes et al.[73] used diode laser-induced NIR fluorescence for detection of ICG in plasma. They demonstrated a detectability of more than two orders of magnitude over absorbance.

Another NIR HPLC application was reported by Kuklenyik,[74] who developed and compared two detectors for NIR fluorescence detection based on a

Figure 12 Optical path of NIR/HPLC fluorescence detector.

Figure 13 Experimental set-up of NIR/HPLC fluorescence detector.

(41)

(42)

silicone photodiode and an APD. The merits of this type of detector were also compared with those of conventional PMT detectors. An HPLC system (SSI gradient system) with a high-pressure pump capable of providing 500 psi pressure controlled by an IBM computer was coupled with an in-house developed excitation and detection system. The experimental set-up of the excitation and detection and the final set-up are shown in Figures 12 and 13. It comprised a silicon photodiode detector coupled with a 24-μL HPLC flow cell shown in Figure 12 and, in the set-up with an APD, a modified Model 4200 LI-COR microscope[41] was used instead of the silicon photodiode. Detector performance was evaluated with two NIRDs, IRD40™ **(41)** and 1,1′,3,3,3′,3′-hexamethyl-4,4′,5,5′-dibenzoindotricarbocyanine perchlorate **(42)**, first without an HPLC column followed by subsequent

Figure 14 Detection of three consecutive injections of IRD40™ on a C_{18} column.

runs with C_{18} HPLC columns. Detector signals for three consecutive injections of IRD40™ at 10^{-10} M concentration are shown in Figure 14. Detection limits of 1.22×10^{-11} and 5.89×10^{-12} M were achieved for the two dyes and the numbers of dye molecules detected were calculated to be 36 500 and 17 600, respectively.[74] The overall results showed that the less expensive, more efficient photodiode was sensitive for detection in the NIR region. The detector was designed to collect signals at 820 nm, and a better match of the dye emission with the detector and better light collection efficiency should help improve the sensitivity much more. Even in the early stage of development in this direction, the NIR fluorescence method shows sensitivity comparable to or better than those of conventional methods. Further evaluations and modifications could help achieve much greater sensitivities.

4.3 Environmental Applications of Near-infrared Fluorescence

The fundamental principle involving the analytical applications of dyes to study the microenvironment essentially involves the changes induced by the analyte that can be directly measured by spectral changes. These changes depend on the concentration of the analyte and the interaction between the analyte of interest and the dye. Typically these probes involve a cation-selective receptor either as an integral part of the chromophore's π-system or covalently attached to the fluorophore via an alkyl tether.[75–77] The coordination of the cation affects the spectral position of absorption and emission bands, molar absorptivity, and, to a smaller extent, the fluorescence quantum yield. The interaction of a metal ion with an organic reagent might result in the enhancement of the fluorescence or the quenching of the fluorescence of the organic reagent in the presence of an analyte. A statistical study showed that about 89% of luminescent methods are based on the enhancement of fluorescence and about 11% are based on quenching reactions.

The investigation of toxic metal ions in the environment has been of growing interest in the past few decades and the decreasing permissible limits for most of these metal ions set by major health organizations such as the World Health Organization (WHO) and the United States Environmental Protection Agency (USEPA) have provided a tremendous thrust for the development of sensitive analytical techniques. Most of the publications devoted to the detection of metal ions by means of spectroscopic techniques used UV/VIS probe molecules such as rhodamine, fluorescein, 8-hydroxyquinoline, and their derivatives.[78–83] Table 8 provides a list of some of the different fluorescent sensors that have been used for the determination of the most commonly studied metal ions, namely Al(III), Be(II), Co(II), Fe(III), and Li^+. Unfortunately, spectral interference is significant in this region. The use of NIRDs is a better alternative.[84–90] The low background interference observed for other molecules in the NIR spectral region together with the longer Raman shift offers better SNRs. Casay et al.[91] investigated tetrasubstituted NPc NIRDs as potential probes for the determination of toxic metal ions. They developed the first NIR optical probe that could detect lead, lithium, and cadmium at parts per billion levels[91] and potassium at 0.566 ppm.[92] More recently, Tarazi[93] reported the detection of metal ions using three novel NIRDs, namely TG 170 **(43)**, NN525 **(44)**, and JCM-15C5 **(45)**. The spectral characteristics of the three dyes are listed in Tables 9–11. They evaluated TG 170 for the detection of Al(III) and Be(II), NN525 for the detection of Fe(III) and Co(II) ions, and JCM-15C5 for the detection of Li^+ in the presence of other interfering ions.

(43)

The hydroxy carboxy functionality of TG 170 **(43)** has a known selective complexation with Al(II) and Be(II) ions. Using this dye, they reported a detection limit of 52 ppb for Al(III) and 24.6 ppb for Be(II) ion. For the NIRD NN525 **(44)**, only Fe(II), Fe(III), and Co(II) ions resulted in quenching of fluorescence. Detection limits of 3.54 ppb for Fe(III) and 1.55 ppb for Co(II) were obtained. The calibration curves obtained for the

Figure 15 Calibration curve for detection of Fe(III) with NN525.

Figure 16 Calibration curve for detection of Co(II) with NN525.

two metal ions are illustrated in Figures 15 and 16. The crown ether functionalized cyanine dye JCM-15C5 **(45)** was used for detection of Li^+ ions in the presence of other interfering ions. They obtained a linear plot of fluorescence intensity for Li^+ amounts ranging from 0.0347 to 0.222 ppb (Figure 17). A detection limit of 0.0743 ppb was reported. The stability constant for the JCM-15C5 complex was higher than those achieved in other studies. The method development represents a significant improvement over conventional methods. Owing to the minimal interferences encountered in the NIR region, it eliminates the need for extensive sample preparation, and additionally it allows for the development of tests that can be carried out at remote sites by rugged compact instrumentation.

Another novel application developed with NIRDs for the detection of Ca^{2+} was reported by Akkaya and Turkyilmaz.[94] They developed a squaraine-based fluorescent sensor for calcium [Scheme 6, **(47)**]. The probe developed was very sensitive to Ca^{2+} concentrations in the

Figure 17 Calibration curve for detection of Li^+ with JCM-15C5 **(45)**.

Scheme 6 Synthesis of Ca^{2+} fluorescent chemosensor [Akkaya and Turkyilmaz[94]].

micromolar range (Figure 18). Signal changes resulting from the loss of the donor alkylamine functions on Ca^{2+} chelation, decreasing the molar absorptivity from 300 000 to 50 000. The λ_{max} of the dye at 698 nm permits the use of an inexpensive commercial laser diode emitting at 690 nm for excitation and a photodiode for detection, opening avenues for the development of compact, rugged systems free from background interferences for cellular ion-flux studies and real-time imaging applications.[94]

Another unique environmental application developed was an NIR phase-resolved fluorescence spectroscopy-based fiber-optic corrosion sensor for the detection of aluminum and iron and their corrosion by-products by Chin et al.[95] The method essentially involves an NIRD that is embedded in a fiber-optic cladding, coupled with appropriate excitation and detectors and integrated with an in-house phase-resolved fluorescence spectroscopy board. A block diagram of the set-up is shown in Figure 19. They studied three in-house synthesized NIRDs, TG1 **(48)**, TG2 **(49)**, and TG3 **(50)** for complexing Al(III) ions. The method was more effective than conventional fluorescence techniques because it measures the lifetime changes of the dye which are independent of the surrounding environment as opposed to fluorescence. Table 12 lists the fluorescence lifetimes for the three dyes in the presence of Al(III) ions. This method developed was very versatile as it could be integrated into airframe and wings of aircraft or other critical failure locations (fasteners, bolts, composite joints, welds) for measuring corrosion. Thereby, strain and structural fatigue can be monitored using NIR technology. The preliminary results obtained were very encouraging and future potential uses of this system could include monitoring composite life cycles and corrosion and structural fatigue of launch pads, rockets, space structures, and advanced aircraft.[96,97]

4.4 Other Applications of Near-infrared Fluorescence

In this section, we describe other analytical applications developed with NIR fluorescence. The first application discussed is the determination of hydrogen ion concentration (pH), which is an important part of many

Figure 18 Emission spectrum of fluorescent chemosensor as a function of Ca^{2+} concentration.

Figure 19 Fiber-optic set-up for phase-modulated fluorescence detection of metal ions.

(48)

(49)

(50)

analytical procedures. The use of fluorescent dyes and indicators for pH measurement is well documented in the literature. A number of indicators with spectral characteristics in the UV/VIS region have been reported,[98–101] but only a few have been reported for pH measurements in the NIR region. Several classes of NIR pH-sensitive dyes have been developed in our laboratories at Georgia State University in collaboration with Strekowski et al.[102–105] Of these pH-sensitive dyes, the most useful include the bis(aminodiene)ones that undergo transformation from the keto form to the cyanine enol form. A pH-sensitive dye **(51)** (Scheme 7) showed distinct bands under acidic and basic conditions (Figure 20). The absorbance maximum at 531 nm undergoes a strong bathochromic shift in acidic conditions with a concomitant change in fluorescence spectra with an absorbance band at 709 nm. The change in absorbance maximum is attributed to protonation of the oxygen atom which induces a shift to the cationic enol form of the dye and restores the cyanine chromophore to give a bathochromatic shift to the NIR region. Another pH-sensitive NIRD **(53)** was evaluated. Representative spectra of the NIRD trapped in Nafion

Table 12 Lifetime data for NIRDs TG1, TG2 and TG3

Dye	Dye concentration (M)	Al(III) concentration (M)	τ (ns)
TG1	3.71×10^{-6}	0.00	0.794
TG1	3.71×10^{-6}	6.32×10^{-3}	0.523
TG2	2.33×10^{-6}	0.00	0.792
TG2	2.33×10^{-6}	6.32×10^{-3}	0.561
TG3	6.59×10^{-6}	0.00	0.387
TG3	6.59×10^{-6}	6.32×10^{-3}	0.455

matrix at different pHs are shown in Figure 21. The changes in the spectra in the pH range 11–12.4 were reproducible. Owing to the extremely acidic environment of the Nafion membrane, the dye provided a useful pH range, which deviated from the pK_a value of the dye alone. This study demonstrated the use of Nafion as a substrate for immobilizing NIRDs and the feasibility of developing an NIR pH sensor.

Scheme 8 Novel pH-sensitive NIR ethoxy adduct of IR-1048 **(54)**.

Mason et al.[105] recently prepared a number of C2-derivatized indolenine NIR chromophores that exhibit unique spectral properties as a function of pH. Of this series, JCM-1048-OEt **(54)** (Scheme 8) was studied by Tarazi.[93] The molecular structure of the dye contains an ethoxy moiety covalently linked to the C2-position of the 3*H*-indole. This addition results in the interference of the cationic delocalization that is typical of cyanine dyes and produces a complex absorption spectrum with a λ_{max} at 511 nm. However, addition of acid regenerates the cationic chromophore IR-1048 **(55)** to give a dramatic red shift to 1050 nm. The spectral characteristics of the dye in different pHs are shown in Figure 22. As can be seen, the dye exhibits two characteristic absorptions, one in the NIR and the other in the UV/VIS region. The dye exhibited a linear range for the NIR peak over the pH range 6–9 in acetone, pH 5–9 in acetonitrile and pH 6–12

Figure 22 Absorption of JCM 1048-OEt **(54)** at different pHs.

Scheme 9 Structure of pH-sensitive NIRD JCM 648/932 **(56/57)**.

in water as the solvent. In addition to the C2-derivatized NIRD, Mason et al.[106] reported the synthesis of a bis(aminodiene)one, JCM-648/932 **(56)** (Scheme 9) that exhibits pH-dependent absorptions in the NIR region. In neutral or basic conditions the equilibrium favors the keto form with an absorbance maximum of 648 nm in methanol. However, addition of acid results in the protonation of the carbonyl to restore the cyanine system. This acidic species **(57)** shows electronic absorption at 932 nm. The transformation from the keto to the enol form is fully reversible and can be carried out repeatedly.

Another application developed using NIR fluorophores is fluorescence detected circular dichroism (FDCD). This method is similar to absorption CD, but fluorescence intensity as opposed to absorbance is the measure of molecular ellipticity. Absorption CD is a valuable tool for examining the molecular chirality of proteins in the ground state. However, owing to the limited number of chiral centers, CD is often limited to qualitative measurements and global conformational changes instead of optical activity about specific centers. Tinoco and Turner reported the ability to circumvent conventional problems with CD measurements by the FDCD technique.[107,108] FDCD can be used to measure the CD of a single contributing chiral fluorophore while avoiding nonfluorescent chiral absorbers and achiral fluorophores.[108,109] For example, fluorescence from a single tryptophan residue has been measured in the midst of other chiral absorbing residues present in proteins. Structural studies of proteins with and without ligand binding have also been reported.[100–112] Similarly to fluorescence spectroscopy, FDCD makes use of a 90° angle relative to the excitation source for detecting the fluorescence. Unlike fluorescence, where plane polarized light is used for excitation, circularly polarized light is used in FDCD. When in the absence of energy transfer and only a single chiral fluorophore exists at the analytical wavelength, the detected FDCD is for a particular population of fluorophores. This situation may be inconceivable in many applications where many proteins may be present in a mixture. In order to avoid complications with matrix interferences, chromatographic techniques have been used in conjunction with FDCD.

Yeung et al.[113,114] reported the use of LIF with FDCD coupled to HPLC and CE. They reported detection limits of 170 and 0.07 pg for riboflavin by HPLC/FDCD and CE/FDCD, respectively. Thomas et al. reported the use of multidimensional FDCD for resolving mixtures without physical separation.[111,112] This method utilized the differences in the excitation and emission bands for resolving the fluorescence spectra of optically active fluorophores. Resolving mixtures of optically active fluorophores based on their fluorescence lifetimes has also been reported.[115,116] Since CD is a weighted-average measurement,[115] many chromophores present in biomolecules contribute to the CD signals. This presents a quantitative limitation in CD measurements. Although the same rules apply to FDCD, intrinsic fluorescence from optically active fluorophores limits the measured CD to a few possible molecules such as tryptophan, tyrosine, and phenylalanine in proteins. However, when chiral nonfluorescent molecules absorb in the ultraviolet (UV) region, the radiation intensity incident on the fluorophore of interest can be weakened. Consequently, the emission intensity may diminish. Considering the lower quantum yields associated with fluorescent protein residues and the number of potential interfering transitions, CD and FDCD at shorter wavelengths are limited.

Long-wavelength alternatives to UV CD measurements have been reported. Keiderling discussed the use of vibrational circular dichroism (VCD), a chiroptical

analog of IR spectroscopy.[117] This technique measures the intrinsic vibrational modes of proteins which avoids some of the limitations of conventional absorbance CD. Sophianopoulos et al. used extrinsic NIR chromophores as structural probes in near-infrared circular dichroism (NIRCD) measurements.[118] Since synthetic probes possessing various properties are readily available, photophysical limitations of intrinsic chromophores can be avoided. Although VCD and NIRCD have the advantage of avoiding biological background interferences, they lack the sensitivity gained in FDCD.

Since there are very few proteins that exhibit long wavelength fluorescence, greater sensitivity, selectivity, and spectral resolution can be gained through the use of near-infrared fluorescence-detected circular dichroism (NIRFDCD) of extrinsic fluorophores. Many biomolecules typically absorb only at lower wavelengths, and thereby complex samples can be potentially analyzed without physically separating matrix components. Typically, NIRDs are optically inactive, low molecular weight (MW $\approx 1000\,\mathrm{g\,mol^{-1}}$) symmetrical compounds that do not yield FDCD. When placed in an asymmetrically perturbed environment, as in protein binding sites, chirality may be induced, resulting in Cotton effects.[118] Therefore, these compounds must meet two criteria in order to exhibit FDCD: first, the molecule must be fluorescent in the NIR region, and second, it must possess induced chirality through noncovalent interactions with the macromolecule clearly indicating that binding has occurred. In our laboratories NIRFDCD was used in order to gain a better understanding of the structure of NIRDs that bind proteins. An understanding of dye binding to albumin may relay important information concerning these dyes as labels or probes in analytical techniques such as the separation of proteins with HPLC, gel permeation chromatography (GPC) or in gel electrophoresis. Meadows et al.[119] recently investigated the NIR squarylium dye NN525 **(44)** as a non-covalent probe for protein structural determinations. This dye, owing to its rigid squarate residue, has greater photostability relative to its cyanine counterpart. They found that it forms a stable complex with serum albumins with binding constant in excess of $10^6\,\mathrm{L\,mol^{-1}}$ compared with $10^5\,\mathrm{L\,mol^{-1}}$ for many other conventional dyes.[120,121] This in turn added to the ease of detection. Also, the high quantum yield and molar absorptivity permit the use of smaller amounts of dye relative to visible counterparts. Preliminary results showed that NIRFDCD of squarylium fluorophores can be measured using 10–100-fold lower dye concentrations in comparison with normal absorbance CD.[119] The advantage of using lower concentrations of dyes simplifies the assessment of competing equilibria associated with high concentrations such as dye or protein aggregation.

Figure 23 Absorption spectra of NN525 **(43)** bound to different proteins.

Figure 24 NIRFDCD spectra of NN525 **(43)** bound to different proteins.

Dye aggregation may in some instances result in the absorption of circularly polarized light.[122]

A common finding for many of the NIRDs previously studied is the enhancement of photophysical properties upon binding to hydrophobic environments (Figure 23).[118,123–125] An increase in these properties permits the use of even lower probe concentrations. This can be advantageous since lower ratios of bound fluorophores can leave proteins virtually unperturbed structurally.

Previous reports by Sophianopoulos et al.[118] support the binding of NIR squarylium compounds to similar, if not identical, binding sites on bovine serum albumin (BSA) with immeasurable conformational changes. Many of the symmetrical NIR compounds do not have measurable optical activity in the protein-unbound state. When these dyes bind in asymmetric binding sites of proteins, induced Cotton effects can occur. As can be seen in Figure 24, the relative FDCD intensities found for the three different albumin–dye complexes is in accordance with the absorbance spectra. This indicates

that those transitions occur through asymmetric perturbations in the fluorophore. Structural differences in the binding sites occupied by NN525 cause intensities to differ. Although not confirmed, previous data supported a common binding site near positively charged amino acid residues.[118] Homology in this site among different species may account for the common negative Cotton effects observed for different albumins. Differences in the hydrophobicities and/or electrostatic interactions at these sites may explain the intensity variations exhibited for the different species. Changes in the extent of the association or weak induced chirality can result from weaker noncovalent interactions. The squarylium dyes had large molar ellipticities (10^5 ° cm^2 $dmol^{-1}$) when bound to BSA. Although induced CD may occur with binding to macromolecules, optical activity due to intramolecular forces, such as dye aggregation[123,126] in aqueous solutions, is less likely at lower concentrations used in FDCD. In many cases these complexes quench fluorescence, but absorb circularly polarized light. Therefore, the CD intensities may falsely indicate asymmetric interactions in the protein-bound dye. The lower concentrations (10^{-7} M) needed in these NIRFDCD studies help prevent solubility limitations that can cause the formation of aggregates, avoiding extraneous Cotton effects. Hence the probability of FDCD data containing artifacts from aggregates is small relative to CD. The use of extrinsic fluorophores in NIRFDCD can provide an abundance of complementary information about conformational changes near the fluorophore. The main mode of binding of NIR squarylium dyes to BSA was determined to be hydrophobic, although electrostatic forces may also contribute. Van der Waals contacts near the dye binding site may enhance their association to proteins. The use of CD in conjunction with tryptophan FDCD in proteins and NIRFDCD of noncovalently bound dyes can provide a more detailed description of protein structure and interactions of proteins with ligands. A further advantage of NIRFDCD, the need for lower concentrations, prevents the occurrence of probe and protein intramolecular interactions, which simplifies data interpretation.

5 CONCLUSIONS

The discussions in this article demonstrate the various advantages of working with the novel emerging technology of NIR fluorescence. Reduction in background interference offered by this method is the greatest advantage. No other analytical method known thus far can compete with the highest possible sensitivity achievable, i.e. single-molecule detection, offered by LIF. NIR detection provides advantages in complex biological and environmental systems where background interference is often a major concern. The availability of commercial NIRDs and NIR instrumentation, although limited, has provided a tremendous advance in the development of applications in this region. The commercial dyes or instrumentation can be tailored to specific applications and aid in interfaces with other commercial instrumentation readily available.

The photostability of NIRDs is a cause for concern. However, recent studies have focused on the development of functionalized photostable NIRDs to overcome this problem. The combination of diode laser excitation sources with photodiodes for detection and coupling of these to suitable fiber-optic interfaces aid in miniaturization and allow for development of remote sensing applications. Time-resolved measurements for discrimination between similar species have made the method very useful both in biological applications such as DNA sequencing, cytology, immunoasssays, and intracellular measurements and in environmental applications in determining metal ions, pH and microenvironment determination. Other areas that utilize the advantages include photodynamic therapy, thermal transfer printing, optical recording, transparent bar codes, and forgery prevention. Progress continues to be made with more applications being developed using the emerging novel NIR fluorescence technology.

Luminescence is a term used for both fluorescence and phosphorescence. These are emission processes following the absorption of light, and the distinction between them is based upon the process of the deactivation mechanism. Phosphorescence has been identified as the light emitted from the triplet excited state to the ground state, a spin-forbidden transition. Fluorescence is a radiational transition between electronic states of the same multiplicity.

The first analytical uses of phosphorescence were published in the 1950s, but the technique was not widely accepted due to the practical aspect of measuring the signal at cryogenic temperatures (77 K).

Developments in room temperature phosphorescence (RTP) have given rise to fundamental and practical advances which have stimulated interest in phosphorimetry. Solid-surface room temperature phosphorescence (SSRTP) has been generally observed by immobilizing the lumiphor on a solid support such as filter paper or polymeric resins. SSRTP has been shown to be a sensitive and selective approach for the analysis of trace components in biological, pharmaceutical, and environmental samples. Techniques such as SSRTP combined with flow injection analysis provide new avenues for optical sensing transduction and improvement of SSRTP techniques. Applications of SSRTP in flowing systems include the sensing of cations, anions, oxygen, glucose, ethanol, antibiotics, and moisture.

A number of developments in RTP have focused on sensitized phosphorescence (SP) and on the use of ordered media (micelles and cyclodextrins (CDs)), allowing the observation of RTP in fluid solution. In SP the triplet energy of a donor (analyte) is transferred to an acceptor that phosphoresces in fluid solution and the emission of the acceptor is measured. Therefore, SP can only provide quantitative information. In ordered media, a micelle (or a CD) protects the long-lived triplet state from the quenching processes that normally take place in solution, allowing both quantitative and qualitative measurements. SP and ordered media RTP provide the limits of detection for many lumiphors in the nmol^{-1} range and calibration graphs have a wide linear range.

As new instrumental and basic insights emerge in SSRTP, Micelle Stabilized Room Temperature Phosphorescence (MSRTP), and solution-sensitized RTP, these techniques will find much greater use in the trace and ultratrace analysis of dissolved, volatile, and gaseous substances in areas such as pharmaceutical analysis, environmental science, and clinical chemistry.

1 INTRODUCTION

Phosphorescence emission has been observed from a variety of compounds and is differentiated from fluorescence by the long-lived emission light after cut off of the excitation source. However, the technique has not became a popular analytical method due to problems arising from the practical aspect of measuring the signal at cryogenic temperatures.

Recent developments in RTP have given rise to both fundamental and practical advances which have stimulated interest in phosphorimetry. Promising experimental designs involve creative composite techniques such as high-performance liquid chromatography/MSRTP detection, SSRTP, RTP optosensing, RTP fiber optic chemical and biochemical sensors and RTP immunoassays, among other possibilities.

Phosphorescence is a complementary technique to fluorescence, allowing a wider range of molecules to be

Encyclopedia of Analytical Chemistry

studied. The sensitivity of phosphorescence is comparable to that of fluorescence; its selectivity is enhanced through the use of excitation and emission wavelengths and by using time discrimination.

The introduction of microelectronics-based phosphorimeters using a pulsed xenon lamp affords easier operation and more sophisticated data treatment using chemometrics.

2 THEORY

2.1 Fluorescence and Phosphorescence

A diagram of the energy levels of a molecule, known as a Jablonski diagram, is shown in Figure 1. Absorption of radiation by a molecule in the lowest vibrational level of the ground state (S_0) results in its excitation to one of the higher energy levels (the lowest, S_1, is called the first excited singlet state). In about 10^{-12}–10^{-14} s, the electronically excited molecule will decay by loss of thermal energy to the lowest vibrational level of the excited states, a nonradiative process known as vibrational relaxation. As the energy gap between excited states is generally small, energy can be transferred from the lowest vibrational levels of S_2 to the highest vibrational levels of S_1. This nonradiative process is known as internal conversion. Eventually, the first excited state (S_1) can be reached by all the excited molecules.

From the lowest vibrational level of S_1, the energy difference to S_0 is usually so great that internal conversion to S_0 has a low probability and is a relatively slow process. In this case, luminescence is observed. Luminescence is the term used for both fluorescence and phosphorescence. In addition to radiative (fluorescence) and nonradiative (internal conversion, vibrational relaxation) pathways, an excited molecule in S_1 can return to the ground state by intersystem crossing to the lowest excited triplet state (T_1). From this level the molecule can again undergo vibrational relaxation to the lowest vibrational level.

Figure 1 Jablonsky diagram.

The triplet state is lower in energy than the singlet state and a molecule in this triplet state can return to the ground singlet state by different processes, namely emission of radiation (phosphorescence) and nonradiative loss. From a theoretical point of view the main difference between fluorescence and phosphorescence is the nature of the electronic transition involved. Fluorescence is a short-lived emission from the lowest vibrational level of the lowest excited singlet state to the ground state, and does not invoke a change of the electronic spin state. This transition is spin allowed and occurs with a high degree of probability. Phosphorescence involves a change in electronic spin, and thus is called a 'forbidden' transition and is highly improbable. As a result, the radiative lifetimes of fluorescence and phosphorescence are very different – for fluorescence it ranges from 10^{-9} to 10^{-7} s (i.e. the same order as the lifetime of an excited singlet state) and for phosphorescence from 10^{-3} to 10 s. Owing to the relative energies of the excited states, phosphorescence occurs at longer wavelengths than fluorescence.

Given the fact that molecules in the triplet state have long lifetimes, the probability of collisional transfer of energy with other molecules (e.g. solvent molecules) is greatly increased. This process is very efficient in solution at room temperature, being the main pathway for loss of triplet state energy. Phosphorescence requires special experimental conditions under which deactivation processes (intra- and intermolecular) are diminished as much as possible. Fluorescence does not require such special conditions.

A more thorough account of the fundamental radiative and nonradiative processes that are encountered in molecular luminescence spectroscopy is given in standard textbooks and monographs.[1–7]

2.2 Kinetics

Fluorescence and phosphorescence both obey a first-order kinetic rate law; however, the kinetics of the emission as phosphorescence is somewhat more complex than that of fluorescence because an intersystem crossing process to the triplet level is involved.[8,9] As only those molecules in the triplet state emit phosphorescence, the emission process may be written as in Equation (1)

$$T_1 \longrightarrow S_0 + h\nu_p \qquad (1)$$

where h is Planck's constant and ν is the phosphorescent wave frequency.

The kinetic rate equation describing the total deactivation of T_1 is given by Equation (2)

$$\text{rate}_p = \frac{d[T_1]}{dt} = -\left(k_p + k_{is}^{ts}\right)[T_1] \quad (2)$$

where $[T_1]$ is the concentration of molecules in T_1 at any time, k_p is the first-order rate constant for phosphorescence emission, and k_{is}^{ts} the rate constant for intersystem crossing (triplet to singlet). The terms k_p and k_{is}^{ts} have the dimensions of time^{-1}. The rate constant k_p is smaller than the corresponding k_f for fluorescence emission and ranges from $0.033\,s^{-1}$ (for aromatic hydrocarbons) to $10^4\,s^{-1}$. Typical k_f values range from $10^5\,s^{-1}$ to $10^9\,s^{-1}$. Therefore, phosphorescence is a relatively slow process and the fraction of excited molecules that emit phosphorescence is small; there are nonradiative competing processes which occur at comparable or greater rates than phosphorescence.

For a first-order process, the lifetime τ is defined as the time at which the emission intensity has decreased to 1/e (or to 36.8%) of its initial value following termination of excitation, and can be expressed as the reciprocal of its rate constant. Thus, the phosphorescence lifetime is (Equation 3)

$$\tau_p = \frac{1}{k_p} \quad (3)$$

and the observed lifetime of the triplet state is (Equation 4)

$$\tau_t = \frac{1}{\left(k_p + k_{is}^{ts}\right)} \quad (4)$$

The phosphorescence quantum yield Φ_p is defined as the ratio of the number of photons emitted to the number absorbed (Equation 5):

$$\Phi_p = \frac{\text{photons emitted as phosphorescence}}{\text{photons absorbed}} \quad (5)$$

In its simplest form, the kinetics definition of Φ_p is (Equation 6)

$$\Phi_p = \frac{\text{rate of emission}}{\text{rate of absorption}} = \frac{k_p[T_1]}{k_{abs}} \quad (6)$$

where k_{abs} is the rate of light absorption. Assuming that no chemical reactions or quenching take place, three processes can deactivate S_1: fluorescence, internal conversion, and intersystem crossing (singlet to triplet), with rate constants k_f, k_{ic}, and k_{is}^{st}, respectively. So, in the steady state, the rate of absorption equals to the total rate of deactivation of S_1 (Equation 7):

$$k_{deact} = \left(k_f + k_{ic} + k_{is}^{st}\right)[S_1] \quad \text{and}$$
$$k_{abs} = \left(k_f + k_{ic} + k_{is}^{st}\right)[S_1]. \quad (7)$$

Substituting this value in Equation (6) gives Equation (8):

$$\Phi_p = \frac{k_p[T_1]}{\left(k_f + k_{ic} + k_{is}^{st}\right)[S_1]} \quad (8)$$

In the absence of quenching, there is a loss of absorbed energy through intersystem crossing (triplet to singlet) and, at the steady state, Equation (9) holds:

$$k_{is}^{st}[S_1] = k_p[T_1] + k_{is}^{ts}[T_1] \quad (9)$$

where k_{is}^{ts} is the rate constant for intersystem crossing (triplet to singlet).

Now, multiplying the right-hand side of Equation (8) by $k_{is}^{st}[S_1]/k_{is}^{st}[S_1]$ gives Equation (10):

$$\Phi_p = \frac{k_{is}^{st}[S_1]}{\left(k_f + k_{ic} + k_{is}^{st}\right)[S_1]} \frac{k_p[T_1]}{k_{is}^{st}[S_1]} \quad (10)$$

Then, substituting Equation (9) and cancellation of $[S_1]$ and $[T_1]$ gives Equation (11),

$$\Phi_p = \frac{k_{is}^{st}}{k_f + k_{ic} + k_{is}^{st}} \frac{k_p}{k_{is}^{ts} + k_p} \quad (11)$$

which is the complete kinetic definition of Φ_p. This expression is the product of the fraction of excited molecules initially in the S_1 state that cross over to the T_1 state (the triplet quantum yield, Φ_T) and the fraction of molecules in the T_1 state that emit a photon (the phosphorescence quantum efficiency, θ_p; Equation 12):

$$\Phi_p = \Phi_T \theta_p \quad (12)$$

2.3 Quenching and the Stern–Volmer Relationship

Another nonradiative pathway of deactivation of an excited singlet or triplet state is quenching.[10–12] Luminescence is said to be quenched when the lumiphor and another species (quencher) interact, accelerating the decay of an excited state to a lower excited state or to the ground state. This interaction may take place in the excited state of the lumiphor and be collisional in nature. In this situation the process is referred to as dynamic quenching. The excitation energy is transferred to the quencher and is nonradiatively dissipated. Alternatively, the lumiphor and the quencher may associate in the ground state, forming a species that does not display the original luminescence characteristics. This process is known as static quenching.

In a phosphorescence measurement, if quenching is included in Equation (3), the rate of deactivation from the triplet state T_1 is (Equation 13)

$$\text{rate}_p = -\left(k_p + k_{is}^{ts} + k_q[Q]\right)[T_1] \quad (13)$$

where $[Q]$ is the quencher concentration and k_q is the bimolecular quenching rate. Thus, the phosphorescence quantum yield in presence of a quencher is (Equation 14)

$$\Phi_p^q = \frac{k_p}{\left(k_p + k_{is}^{ts} + k_q[Q]\right)} \frac{k_{is}^{st}}{\left(k_f + k_{ic} + k_{is}^{st}\right)} \quad (14)$$

Dividing Equation (11) by Equation (14), the ratio of quantum yields in the absence of quencher (Φ_p) and in the presence of quencher (Φ_p^q) yields Equation (15):

$$\frac{\Phi_p}{\Phi_p^q} = \frac{k_p + k_{is}^{ts} + k_q[Q]}{k_p + k_{is}^{ts}} = 1 + \frac{k_q}{k_p + k_{is}^{ts}}[Q] \quad (15)$$

Using Equation (4),

$$\frac{\Phi_p}{\Phi_p^q} = 1 + k_q\tau_t[Q] = 1 + K_q[Q] \quad (16)$$

Equation (16) is known as the Stern–Volmer relationship, in which K_q is the Stern–Volmer quenching constant and τ_t is the observed triplet lifetime in the absence of quencher. This equation states that plots of Φ_p/Φ_p^q versus $[Q]$ should be linear with a slope equal to K_q. In the case of dynamic quenching, the slope of the plot, K_q, is $\tau_p k_q$. For static quenching K_q is the binding constant of the ground-state complex between the phosphor and the quencher.

Generally, the quencher concentration is always much larger than the concentration of excited molecules being quenched. Then, the product $k_q[Q]$ may be considered a constant as $[Q]$ is not substantially modified during the quenching process. In this case, the product $k_q[Q]$ may be defined as a ''pseudo-first-order rate constant'' and the triplet state lifetime in the presence of quencher τ_p^q is (Equation 17)

$$\tau_p^q = \frac{1}{\left(k_p + k_{is}^{ts} + k_q[Q]\right)} \quad (17)$$

The oxygen molecule in its stable ground state is paramagnetic, having two unpaired electrons in different orbitals. Such an electronic configuration, called a triplet, is unusual for ground-state molecules. Oxygen in this state is a potent quencher, especially of the triplet states, quenching almost all organic phosphors.

Oxygen quenching is diffusion limited and may be described by a modified Stern–Volmer relationship which holds for both fluorescence and phosphorescence and for both lifetimes and intensities (Equation 18):

$$\frac{I_0}{I} = \frac{\tau^0}{\tau} = 1 + k_q\tau^0[O_2] \quad (18)$$

in which I_0, τ^0 and I, τ are the intensities and lifetimes in the absence of oxygen and at an oxygen concentration $[O_2]$, respectively. In the most simplistic terms, Equation (18) means that when O_2 interacts with a lumiphor it decreases the luminescence intensity and shortens its lifetime.

3 INSTRUMENTATION

The equipment required for measuring phosphorescence intensities, lifetimes, excitation and emission spectra are commercially available. Those instruments may be used in low-temperature phosphorescence, MSRTP, and SSRTP, as well as in solution-sensitized RTP work, with no or minor instrumental modifications.[7,12,13]

The major components of fluorescence and phosphorescence instrumentation include a source for exciting radiation, an excitation wavelength selector system, a sample cell, an emission wavelength selector system, and a detector (Figure 2).

Taking advantage of its long lifetime, phosphorescence can be measured in the absence of fluorescence by using a phosphoroscope, a device which allows excitation light to be gated in time.[14] Therefore, if incident radiation is cut off, prompt fluorescence and direct scattering cease almost immediately. However, phosphorescence remains and can be detected free of interference from fluorescence for some time afterwards. Two types of shutter systems are commonly employed:

- The Aminco–Keirs phosphoroscope, in which the sample cell is surrounded by a rotating cylinder with two diametrically opposite apertures. The emitted phosphorescence is collected at right angles to the excitation radiation. The delay between excitation and emission is determined by the speed of rotation and the length of each observation which is determined by the size of the window.
- The Becquerel phosphoroscope, in which the sample cell is placed between two circular rotating discs with opposing 90° sectors cut out of each disk. The duration of each burst of radiation and the delay between them are determined by the speed of rotation. Unlike

Figure 2 Layout of a typical phosphorescence spectrometer.

the Aminco–Keirs phosphoroscope, this shutter system requires 180° geometry and is not so extensively used. Earlier phosphorimeters used these mechanical chopping systems with a continuous excitation source (e.g. xenon arc lamp, a high-pressure mercury lamp or a tungsten incandescent lamp).

Instrumentation for improved acquisition and analysis of phosphorescence lifetime decays have come to the fore with the increasing use of microprocessors and pulsed sources in luminescence works.

Figure 3 illustrates three cycles of sample excitation and observation for a pulsed-source-gated-detector phosphorimeter. With an initial pulse of source energy, with a duration t_f (typically about 10 μs), the phosphorescence intensity reaches a maximum value and then decays exponentially. At a delay time t_d, after which the source flash has decayed, the photomultiplier detector is turned on, and the integrated phosphorescence signal is measured during the on time (t_g). The photomultiplier detector is then turned off and the sequence repeated. Pulsed source-time resolved phosphorimetry was first proposed by Fisher and Winefordner in 1972.[15]

The advantages of pulsed-source-time-resolved phosphorimeters over conventional instruments with mechanical modulation are:

- A higher source peak intensity can be produced during the pulse without overheating the lamp as the thermal energy is dissipated during the dark periods between the pulses.
- The possibility of improving selectivity for a short-lived phosphor compared to a long-lived phosphor.
- The possibility of measuring phosphors with short lifetimes (0.1–50 ms).[16] The performances of mechanical systems are limited by the maximum speed of rotation available.
- Control over the timing parameters allows the analytical potential of phosphorimetry to be extended, such as the possibility of analyzing mixtures of phosphorescent compounds having different lifetimes.

Figure 3 Timing sequence of events occurring during three cycles of sample excitation in a phosphorimeter employing a pulsed radiation source and t_f: width of pulse at half height, t_g: width and t_d delay time between start of pulse and observation.

4 OPERATING PRINCIPLES AND APPLICATIONS

4.1 Low-temperature Phosphorimetry

Low-temperature phosphorimetry from solutions was considered for years as the way of obtaining analytically useful phosphorescence signals. However, low-temperature phosphorescence has not become a popular analytical method because of the need for cryogenic cooling, the irreproducibility of the formation of the cooled matrix, and the problems related to sample introduction into the phosphorimetric system.[17]

Up to the present time, the immersion method has been widely used for cooling the sample, which is lowered into a quartz Dewar flask filled with a coolant. Among the possible coolants (liquid nitrogen, oxygen, rare gases, air) only liquid nitrogen is safe, inexpensive and pure enough to be non-luminescent and transparent at all wavelengths between 200 nm and 800 nm.

Depending on the rate of sample cell cooling and the chemical nature and composition of the solvent system, the cooled matrix can be a clear glass, a cracked glass, or a snow. When the capillary tube makes contact with liquid nitrogen, the sample cools very quickly, and cracked glasses or snows result for most solvents. This problem can be avoided if the capillary tube is gradually cooled over the liquid nitrogen before contact is made.

Only a few solvents form clear glasses at low temperature, the most notable being ethanol, isopentane, and *n*-propanol. However, several solvents that are not useful alone do form good mixed solvents. So, ethanol has been combined with a variety of other solvents, the most popular of the mixed solvents being EPA, a 5:5:2 (by volume) mixture of ether, isopentane, and ethanol.

The above practical disadvantages can be minimized by using a device based on conduction cooling of a short capillary sample cell in a copper block cooled by liquid nitrogen. These devices allow improved sample turnover time to about one sample per minute, it is not necessary to handle Dewar flasks, and the amount of liquid nitrogen is reduced. Unfortunately, it is difficult to obtain good thermal contact between the sample cell and the copper block. Also, it is not easy to thermally insulate the cooling device, which results in difficult quantitative analysis due to fogging of the view area.

4.2 Solid-surface Room Temperature Phosphorimetry

Roth[18] in 1967, first listed the RTP detection limits of 18 organic compounds adsorbed on filter paper. Since this report, the field of analytical SSRTP has expanded considerably.[19–23] Only certain materials are useful for inducing RTP from adsorbed phosphors, among which filter paper is the most widely used. Nearly all of the solid materials employed to develop RTP give phosphorescence background signals. Only sodium acetate has a low background emission. Thus one criterion for selection of a solid surface is to measure the relative RTP signal of the sample compared to the background RTP of the solid surface. Vo-Dinh[13] compared about 20 different kinds of commercial filter papers using pyrene as a model analyte. It was found that the difference in performance between papers was substantially less than an order of magnitude.

In RTP work, the solvent used to deposit the phosphor on the solid substrate can influence the final RTP signal. Acidic, alkaline and neutral solutions have been used in a number of applications. Also, ethanol–water mixtures have been extensively employed. In order to produce spots yielding rapid and reproducible results, a microsyringe or a micropipet is used to deliver the sample to the surface. Once the phosphor is spotted on the solid surface, it is necessary to dry the adsorbed sample prior to the RTP measurement step. In fact, moisture is one of the main factors that drastically diminish the RTP signal. There are different ways to dry the sample: blowing hot air onto the sample, placing the sample inside a desiccator, heating the sample inside an oven, or placing the sample under an infrared heating lamp. The use of an infrared heating lamp has been found to be very practical as the method is rapid (3–5 min compared with 1–5 h in a desiccator), convenient and, usually, nondestructive. The dry sample is kept dry during RTP measurement by passing a flow of air, nitrogen, or argon through the sample compartment. The main steps of an RTP assay are shown in Figure 4 for the method using filter paper.

There is no general model that explains the interactions required to develop RTP from compounds spotted on solid supports. It has been proposed that hydrogen bonding of polar or ionic organic compounds to the hydroxyl groups of the paper (or to the surface silanol groups of silica gel) is the main mechanism that provides the rigidity required to restrict collisional quenching of phosphor molecules in the triplet state. In this single working model, the moisture effect is explained by assuming that water molecules disrupt the hydrogen bonding, thus facilitating oxygen accessibility to the phosphor in the sample matrix.

So far, the analytical potential of SSRTP has been hampered by its discontinuous character, the necessary sample manipulation, support background, and water/oxygen quenching, which limit conventional practical work. Attempts have been made to develop an automatic instrument for SSRTP based on a continuous filter paper on which the samples were sprayed using a conventional atomic absorption nebulizer (Figure 5).

Promising uses for SSRTP include the development of fiber optical chemical sensors. Campiglia and Vo-Dinh[24] have reported the development of a universal RTP sensor adaptable to different analytical situations involving phosphorescent compounds. Filter paper

pretreated with thallium(I) acetate was used as a solid support to increase phosphorescence emission from several model polycyclic aromatic hydrocarbons (PAHs) and nitrogen heterocyclic compounds. Advantage was taken of coupling fiber optics into a pulsed nitrogen laser excitation source to measure RTP emission from compound imbibed on the filter paper. Detection limits at the nanogram per liter level were estimated for all the compounds studied. Reproducibility, highly dependent on drying conditions, ranged from 6.1% for chrysene to 11.9% for 7,8-benzoquinoline. Linear dynamic ranges extended over 2–3 orders of magnitude.

In spite of the generally accepted idea that water adversely affects SSRTP, it has been demonstrated that analytically useful SSRTP can be observed in a continuous aqueous flow provided that the solid support is adequately selected for a given phosphor. The solid support is conveniently packed into a flow cell and the analyte introduced into the flow system, either continuously or by means of an injection valve. The approach involves the integration of the basic reaction/retention/detection processes at the solid support in the flow cell. This detection principle in flow analysis is known as *optosensing* at active surfaces.

RTP optosensing is an important new development in phosphorimetry. Not only can conventional organic phosphors be determined, but also metal ions, anions, surfactants, antibiotics, gases, and vapors (e.g. oxygen, humidity). The favorable analytical performance of RTP optosensing systems for oxygen, allows its use as an optical transducer for enzymatic biosensing in oxygen-mediated reactions, both in solution (e.g. glucose determination) or in a gaseous environment (e.g. ethanol determination; Table 1). It is clear that the combination of flow analysis and SSRTP offer promising new analytical possibilities to phosphorimetry, particularly in the field of optical sensing.[36]

4.3 Room Temperature Phosphorescence in Ordered Media

4.3.1 Organized Surfactant Assemblies: Micelle Stabilized Room Temperature Phosphorescence

Surface active agents (surfactants) are amphiphilic molecules in which a polar head group is attached to a long nonpolar chain. The nonpolar moiety is usually a hydrocarbon tail and the polar region, the head, can be either an ionic or a polar neutral group. These amphiphilic molecules associate dynamically in solution to form relatively well-defined assemblies termed micelles. Micelle formation starts at a characteristic surfactant concentration, the critical micelle concentration (CMC). In aqueous solution, individual surfactant molecules aggregate in such a way that the hydrophobic tails are packed together, forming a nonpolar core, while the hydrophilic heads face the aqueous solution, forming a boundary surface between the core and the isotropic aqueous solution.

An understanding of the organized assembly effect, together with the knowledge of the degree of interaction between the organized medium and the luminescence system being examined, are the keys in developing new analytical luminescence methodologies. In fact, the degree and type of binding between any lumiphor-organized system combination depend on the hydrophobic–coulombic net interactions. These are determined by the relative chemical nature of the luminescent probe and that of the organized medium considered. In this sense, localization of a lumiphore in a given micellar medium may be in any or all of several regions of the aggregate. An amphiphilic solute may align itself with the polar portion in the surface layer of the micelle with the tail directed inward, towards the core of the micelle. Ionic species with an opposite charge to the micellar aggregate may be bound to the micellar surface by electrostatic attraction. Nonpolar species may penetrate to a particular depth into the surface layer.

Table 1 RTP chemical and biochemical optosensing

Analyte	Solid support	Phosphor	LOD	RSD (%)	Ref.
Aluminum	Dowex 1 × 2-100®	Al-ferron	$2\,\mu g\,L^{-1}$	3.2	25

LOD, limit of detection; RH, relative humidity.

Normal micelles have been the organized media more commonly used to develop analytically useful RTP in fluid solutions. In a conventional experiment, the luminescent molecule is dissolved in a sodium lauryl sulfate (SLS) micellar solution and then diluted with thallium lauryl sulfate (TlLS)/SLS solution to obtain a total detergent concentration of $0.10\,mol\,L^{-1}$ and a 30 : 70 ratio of Tl/Na. The solution is finally deoxygenated by purging with nitrogen for 15–20 min and analyzed using time discrimination.

4.3.2 Principles and Applications of Micelle Stabilized Room Temperature Phosphorescence

MSRTP was first reported by Kalyanasundaram et al.[37] Cline Love and Weinberger[38] showed that three fundamental requirements are necessary to develop analytically useful MSRTP for most lumiphors: securing the presence of micellar aggregates (using a surfactant concentration above its CMC), the presence of a heavy atom or a heavy species, and securing oxygen removal.

RTP can be observed from many molecules in fluid solution by incorporating the phosphor into a micellar system. The protective effect of the micellar microenvironment greatly minimizes collisional deactivation of triplet species by restricting their diffusive motions. Only at surfactant concentrations well above the CMC is the protective effect on phosphorescence observed (micellar effect). An additional factor that favorably influences the RTP observed is the relative micelle/phosphor polarity and/or charge. So, no MSRTP is observed in anionic micellar media for negatively charged molecules. However, these negatively charged phosphors experience, in a cationic micellar medium, attractive electrostatic interactions acting concurrently with the hydrophobic ones to provide the necessary immobilization for the observed strong RTP signals.

However, micelles can be functionalized with a heavy atom; for example, the countercation of anionic micelles can be replaced by a heavy element such as silver or thallium. The local effective concentration of the heavy atom in the micelle is then larger than its actual molar concentration. The intrinsic proximity between the phosphor solubilized in the micelle and the heavy counterions results in a heavy atom effect, thus enhancing the rate of intersystem crossing. It is known that the presence of heavy atom perturbers results in shorter phosphorescence lifetimes and causes a considerable reduction of fluorescence emission. Adequate choice of surfactant assemblies and heavy atoms allows one to observe analytically useful MSRTP from a variety of compounds. For example, MSRTP has been observed from polynuclear aromatic and heterocyclic compounds solubilized in SLS anionic micelles and in the presence of thallium, silver, or lead as heavy atom perturbers.[38]

Oxygen is a potent quencher of the excited triplet state. Micellar media provide a microenvironment that can protect a solubilized phosphor from interactions with oxygen allowing for MSRTP in some solutions that have not been deoxygenated. In order to enhance MSRTP, oxygen removal is usually carried out by using an inert gas (e.g. nitrogen). Diaz-Garcia and Sanz Medel[39] studied in detail the use of sodium sulfite as a chemical oxygen scavenger for MSRTP (Equation 19).

$$2SO_3^{2-} + O_2 \longrightarrow 2SO_4^{2-} \qquad (19)$$

The method is simple and reliable. The analytical performance of MSRTP with sulfite deoxygenation was tested for determination of arenes,[40] metals (Table 2), nucleic acids[45] as well as for immunoassays.[46] This simple technique can be extended to chemical deoxygenation of other organized media such as vesicles and CDs to develop RTP in solution,[47] as well as in flowing systems.[48] MSRTP provides limits of detection for many aromatic molecules in the nanomole per liter range and calibration graphs have a wide linear range. The overall precision is about 5%. It is worth mentioning the high sensitivity observed if one considers the high probability of nonradiative pathways that may occur in solution at room temperature.

Cline Love and Weinberger[38] have demonstrated that MSRTP techniques can be applied for detection of phosphors in liquid chromatography in two different approaches:

- Using the micellar solution as a mobile phase. A liquid chromatography/MSRTP procedure for

Table 2 Analytical figures for metal ion MSRTP determination

Metal ion	Reagent medium	λ_{exc} (nm)	λ_{em} (nm)	pH	LOD ($ng\,mL^{-1}$)	RSD (%)	Ref.

CTAB, cetyl trimethyl ammonium bromide.

different PAHs was described in detail using an SLS/TlLS (70%/30%) micellar mobile phase and a propylcyano-bonded column as stationary phase. Detection limits were in the nanogram range for PAHs investigated in coal liquids and wastewater products. Working ranges covered more than three orders of magnitude.

- In a postcolumn addition mode, the micellar phase is merged with the mobile phase after chromatographic separation, as demonstrated for aromatic compounds.

Detergents have also been used in paper-substrate RTP, leading to signal enhancements in the twofold to ninefold range for PAHs adsorbed on filter paper impregnated with Tl/SLS. The main interactions proposed in this system do not involve the presence of micelles but the enhancement is due to improved heavy atom/phosphor proximity and to an increased migration of the species through the cellulose pores of the paper.

4.4 Cyclodextrin Room Temperature Phosphorescence

CDs are cyclic oligosaccharides composed of α-(1 $\rightarrow$ 4)-linked D-glucopyranose units forming thus a truncated cone-shaped structure with a central cavity. The best-known members of this class of natural products are α-, β-, and γ-CDs, as they are commonly referred to, composed of six, seven, and eight glucose units, respectively. The hydrophilic hydroxyl groups of the glucose units occupy both rims of the cone, rendering the CDs soluble in water, whereas the cavity, lined by hydrogen atoms and the glycosidic oxygen bridges, is relatively hydrophobic compared to water. Thus, CDs provide a microheterogeneous environment in water. The unique structural features of the CD cavity explain some of the unusual characteristics of these compounds.

Because of these structural properties, CDs can form inclusion complexes with guest molecules that fit into the cavity, even if only partially. Complexation is based on a combination of several intermolecular interactions, including hydrophobic, electrostatic and dipole–dipole interactions, dispersive forces, steric fit, and hydrogen bonding.

As a consequence of inclusion-complex formation, the microenvironment around the guest molecule in the CD cavity is different from that in the bulk media. In fact, inclusion of a lumiphor in a CD cavity results in important changes in the photophysical and/or photochemical properties of the guest. Analytical luminescence benefits that result from complexation with CDs include:

- Protection of excited states from collisional quenching and other nonradiative pathways. The cavity of the CD is a finite space in that, once it has been occupied by a lumiphor, other molecules are excluded from occupying the space at the same time. This prevents collisional encounters. Also, constraints imposed on the mobility of the guest reduce the rate of the radiationless transition of excited singlet and/or triplet states.
- Solubility enhancement of poorly water-soluble lumiphors.
- Partial protection of phosphor guests against quenching by dissolved oxygen in solution.

Although cyclodextrin room temperature phosphorescence (CDRTP) has not been widely used as an analytical technique, CDs have significant potential as ordered media to develop new RTP methodologies in solution. As in MSRTP, a heavy atom (external or intramolecular) or a heavy structure (e.g. 2-bromoethane) should be present to populate the triplet state. Sample deoxygenation, either using a chemical scavenger as sodium sulfite or bubbling an inert gas, results in increased phosphorescence intensity.

In a conventional experiment for CDRTP analysis of PAHs an aliquot of the analyte of interest is added to a flask and the solvent is removed by gently heating on a hotplate. An aliquot of 1,2-dibromomethane (heavy atom perturber) is then added, followed by dilution with 0.01 mol L^{-1} aqueous CD solution. After shaking vigorously by hand, a cloudiness in the solution can appear due to precipitation of excess 1,2-dibromomethane complexed by CD. This turbidity has no influence on the reproducibility and quality of RTP spectra. Finally, the sample is de-areated for about 15 min with nitrogen and placed in a standard fluorescence cell with a Teflon® stopper for RTP measurement. Following this method, sample preparation time is about 20 min.

4.5 Sensitized Room Temperature Phosphorescence in Liquid Solutions

Direct solution room temperature intensities are generally too low to be analytically useful. Donkerbroek et al.[49] applied the technique of SP in liquid solutions as a useful alternative to direct solution RTP.

In SP the analyte (a weakly or nonphosphorescent species) is excited by means of light absorption. Subsequently, the analyte transfers its triplet energy to an acceptor molecule, thus producing an acceptor triplet with a high phosphorescent yield (Figure 6).

Sensitized RTP is observed under the following conditions:

- When the triplet state energy of the acceptor is lower than that of the donor and when the energy gap

Figure 6 Diagram showing the SP process. The donor (analyte) is excited to the S_2 electronic level (1); then, internal conversion (2) and intersystem crossing (3) can take place. Subsequently, energy transfer to a suitable acceptor having a triplet energy lower than that of the donor occurs (4) and, eventually, phosphorescence of the acceptor is observed. Straight arrows refer to radiative processes and wavy arrows to nonradiative ones.

between the donor and acceptor triplet states is sufficiently high to prevent significant reverse transfer mechanisms.

- When the lifetime of the donor excited state is longer than the energy transfer process in the solvent under consideration. The energy-transfer efficiency $\theta_t^{D,A}$ is given by Equation (20):[49]

$$\theta_t^{D,A} = \frac{K_t[A]}{\left(1/\tau_t^D + K_t[A]\right)} \tag{20}$$

where K_t is the rate constant of the bimolecular energy-transfer reaction, τ_t^D is the triplet lifetime of the donor (D) in the absence of the acceptor A, and [A] is the acceptor concentration. Therefore, appreciable sensitized RTP will occur if $K_t[A] > 1/\tau_t^D$. This condition can be met if solvent deoxygenation is carried out.

- If absorption of excitation radiation by the acceptor is negligible.
- If there is an appreciable population of the donor's triplet state.

Sensitized RTP has been observed for a variety of organic species (drugs, polynuclear aromatics, etc.) and compounds that do not fluoresce in liquid solutions. However, only about 10–15% of the molecules that meet the energy requirements are found to undergo SP. The potential acceptors found useful in sensitized RTP are limited, with biacetyl and 1,4-dibromonaphthalene being the acceptors of choice in many applications.

Sensitized RTP has been successfully applied as a detection method for both chromatographic and continuous-flow systems, and the approach can be considered as complementary to fluorescence detection. Spectroscopically, a drawback of sensitized RTP is that all spectral information about the donor is lost as the emission spectrum is that of the acceptor. The advantages of using SP are:

- The emission wavelength is constant because, for all donors, the same emitting species is employed.
- Analytes are detected at a relatively long emission wavelength of the acceptor, which results in minimizing the effects of background fluorescence and stray light.
- In principle, the approach could be useful for those compounds that phosphoresce in cryogenic conditions, because the primary condition to be fulfilled is an efficient triplet formation.

A complimentary technique with less requirements is quenched RTP in liquid solutions, in which quenching of biacetyl phosphorescence by the analyte acceptors is used to determine the latter.

For sensitized RTP a suitable wavelength is used for analyte excitation and biacetyl phosphorescence is detected. However, in quenched RTP a wavelength is selected where the molar absorptivity of biacetyl is relatively high and it is the only species excited. Thus, the analyte (acting as an acceptor) leads to a decrease of the biacetyl RTP.

Donkerbroek et al.[50] derived Equation (21),

$$\frac{1}{I'_{dir}} = \frac{1}{I_{dir}} + \frac{k_q[Q]}{I_{abs}^B \theta_{isc}^B k_p^B} \tag{21}$$

where I_{dir} is the direct RTP intensity of biacetyl in the absence of quencher (analyte), I'_{dir} is the RTP of biacetyl in the presence of quencher, k_q is the bimolecular rate constant of the quenching reaction, [Q] is the quencher concentration, I_{abs}^B is the rate of light absorption by biacetyl, θ_{isc}^B is the triplet formation efficiency of biacetyl, and k_p^B is the rate constant of the phosphorescence process.

As indicated by this equation, a straight line with a slope proportional to k_q and an intercept equal to the inverted intensity of the nonquenched signal is obtained by plotting $1/I'_{dir}$ versus [Q]. Therefore, for a particular analyte the sensitivity of the quenched RTP is proportional to the k_q value. Donkerbroek et al.[50] estimated the limit of detection (LOD) for various compound classes by quenched RTP using Equation (22):

$$\mathrm{LOD(M)} = \frac{10}{k_q(\mathrm{M^{-1}\,s^{-1}})} \tag{22}$$

Therefore, determination of k_q for a number of analytes is of importance to evaluate the analytical potential of the approach. Quenched RTP in solution

holds considerable potential for use in continuous-flow detector systems. It can also be applicable to many compounds that may have inherently poor detection properties by other techniques. For example, it could be used for nonultraviolet-absorbing species detection in ion chromatography (nitrite, sulfite, *cis*-platin, etc.).

5 TECHNIQUES OF LIFETIME MEASUREMENTS

The commonly used approaches to measure luminescence lifetimes are time-resolved and phase-resolved measurements.[7]

5.1 Time-resolved Measurement

In this method a pulsed radiation source excites the sample and the decay profile is monitored. If the excitation pulse is of very short duration (10 μs) and assuming that only a single decaying component is present, the emission is a monoexponential decay (Equation 23)

$$I_{(t)} = I_0 e^{-t/\tau} \tag{23}$$

where $I_{(t)}$ is the phosphorescence intensity of the compound at a delay time t, and I_0 is the phosphorescence intensity at time $t = 0$. The luminescence lifetime τ is the mean excited state lifetime.

For a binary system of components A and B, the theoretical expressions for pulsed-source phosphorimetry are (Equation 24)

$$\begin{aligned} I_t^{(A)} &= I_0^{(A)} e^{-t/\tau_A} \\ I_t^{(B)} &= I_0^{(B)} e^{-t/\tau_B} \\ I_t^{(A+B)} &= I_t^{(A)} + I_t^{(B)} \end{aligned} \tag{24}$$

where $I^{(A+B)}$ is the total phosphorescence intensity of the mixture. For multicomponent systems similar expressions may be derived.

This technique has important advantages over simple intensity measurements as it involves comparing the luminescence intensity at various times, it is self-referencing, and it compensates for factors such as changes in the efficiency of the source, detector, or electronics.

The three methods generally used to determine phosphor concentrations by time-resolved phosphorimetry are the multiple analytical curve method, the exponential method, and the logarithmic decay time method.[12]

Time-resolved phosphorescence for organic compounds is now well established and was first suggested by Winefordner in 1969.[51] Application of chemometric techniques to the interpretation of RTP emission spectrum–decay data and to simultaneous determination of organic[52] and inorganic[53] species has also been reported recently.

5.2 Phase-resolved Measurement

This method allows phase resolution of the phosphorescence signal from phosphors with different lifetimes. The sample is excited using a source (usually a continuous-wave laser) whose light intensity is modulated at a frequency f.

Table 3 summarizes the equations derived by Aaron and Winefordner, describing the phase and frequency characteristics of luminescence.[54]

Phase-resolved phosphorimetry is especially useful for strong phosphors or concentrated solutions of weak phosphors if fluorescence or stray light interferences are not present. Also, it is adequate for short time analysis (<1 ns) of molecular decays, as the relative error decreases slightly with the faster decay times of the sample under study.

Table 3 Theoretical expressions for phase-resolved phosphorimetry

Total luminescence intensity	dc term	ac term
	$I_L = k_L I_0' + m_L k_L I_0'' \cos(wt - \theta_L)$	
Individual intensities		
Fluorescence	$I_F = k_F I_0' + m_F k_F I_0'' \cos(wt - \theta_F)$	
Phosphorescence	$I_P = k_P I_0' + m_P k_P I_0'' \cos(wt - \theta_P)$	
Frequency functions of the ac term of phosphorescence	Degree modulation	Phase-shift angle
	$m_P = (1 + 4 - \pi^2 f^2 \tau_P^2)^{-1/2}$	$\theta_P = \tan^{-1}(2\pi f \tau_P)$

k_L, k_F and k_P are factors taking into account the quantum efficiency and concentration factors for total luminescence, fluorescence and phosphorescence, respectively; I_0' and I_0'' are the constant-intensity term and sinusoidally varying intensity term of the exciting light function $I_0(t)$, respectively; m_L, m_F, and m_P are the degrees of modulation of total luminescence, fluorescence, and phosphorescence respectively; θ_L, θ_F, and θ_P are the phase-shift angles (in degrees) of the total luminescence, fluorescence, and phosphorescence respectively; τ_P phosphorescence lifetime (seconds); w = angular frequency (hertz); f = linear frequency (hertz). ac, alternating current; dc, direct current. 6 CONCLUSIONS

In spite of the fact that analytical applications of phosphorescence have been somewhat scarce in the past, the examples quoted in this article indicate the variety of possibilities for developing new highly selective, sensitive, simple and rapid phosphorimetric methodologies. With the recent advances in RTP, the introduction of new instrumentation, and the breadth of potential applications, the use of analytical phosphorimetric approaches is likely to increase.

The majority of effort in the future should go into the process of translating research findings into practical applications and/or commercially viable systems. Areas such as miniaturization and development of portable phosphorimeters, and the design and construction of phosphorimetric sensors to monitor analytes in a continuous way, should also deserve special attention, particularly in clinical chemistry and pharmaceutical and environmental fields.

ABBREVIATIONS AND ACRONYMS

ac	Alternating Current
CD	Cyclodextrin
CDRTP	Cyclodextrin Room Temperature Phosphorescence
CMC	Critical Micelle Concentration
CTAB	Cetyl Trimethyl Ammonium Bromide
dc	Direct Current
EPA	Mixture of Ether, Isopentane, and Ethanol
LOD	Limit of Detection
MSRTP	Micelle Stabilized Room Temperature Phosphorescence
PAHs	Polycyclic Aromatic Hydrocarbons
RH	Relative Humidity
RTP	Room Temperature Phosphorescence
SLS	Sodium Lauryl Sulfate
SP	Sensitized Phosphorescence
SSRTP	Solid-surface Room Temperature Phosphorescence
TlLS	Thallium Lauryl Sulfate

The physical and chemical characteristics of surfaces along with the structure and dynamics of molecules near surfaces or interfaces have recently become critically important. Surface measurements have provided important information concerning the properties of the surfaces and the surface/adsorbate interactions. The physical, chemical and biological sciences have benefited tremendously from these studies, with significant developments being made in the areas of diagnostic devices, optical devices, electronic devices and sensors.

The specific behavior of macromolecules at or near surfaces, interfaces, and membranes is currently of primary interest in the biological sciences. Important applications include: adsorption of blood proteins on biomaterials in thrombogenesis research; the binding to and triggering of living cells by hormones, neurotransmitters and antigens; cell adhesion to various surfaces; the mechanism of electron transport in mitochondrial and photosynthetic membranes; and also reaction rate enhancement with membrane receptors by nonspecific adsorption and surface diffusion of ligands. However, investigation of biomolecular behavior at surfaces and interfaces remains a difficult task. Most of the common analytical methods available for investigation of surfaces either lack the extent of surface selectivity required or demand relatively harsh sample handling that severely limits the biological relevance of any results obtained. This article specifically describes ultraviolet/visible (UV/VIS) absorption and photoluminescence techniques applicable to analysis of surfaces or thin films.

1 INTRODUCTION

The physical and chemical characteristics of surfaces along with the structure and dynamics of molecules near surfaces or interfaces have recently become critically important. Surface measurements have provided important information concerning the properties of the surfaces and the surface/adsorbate interactions. The physical, chemical and biological sciences have benefited tremendously from these studies with significant developments being made in the areas of diagnostic devices, optical devices, electronic devices and sensors.

The specific behavior of macromolecules at or near surfaces, interfaces, and membranes is currently of primary interest in the biological sciences. Important applications include: adsorption of blood proteins on biomaterials in thrombogenesis research; the binding to and triggering of living cells by hormones, neurotransmitters and antigens; cell adhesion to various surfaces; the mechanism of electron transport in mitochondrial and photosynthetic membranes; and also reaction rate enhancement with membrane receptors by nonspecific adsorption and surface diffusion of ligands. However, investigation of biomolecular behavior at surfaces and interfaces remains a difficult task. Most of the common analytical methods available for investigation of surfaces either lack the extent of surface selectivity required or demand relatively harsh sample handling that severely limits the biological relevance of any results obtained.

The two general areas of electron and optical spectroscopies are both powerful tools for examining surfaces and studying interfaces. Electron spectroscopy mainly includes techniques such as X-ray photoelectron spectroscopy (XPS), Auger spectroscopy and secondary-ion mass spectrometry (SIMS). The main optical spectroscopy techniques are attenuated total reflectance (ATR), total internal reflection fluorescence (TIRF), total internal reflection Raman (TIRR), surface-enhanced Raman spectroscopy (SERS) and ellipsometry. This article is mainly concerned with the application of ATR and TIRF spectroscopy in the ultraviolet (UV) and visible (VIS) wavelength range for surface studies of molecular species. The most comprehensive treatment of the

Encyclopedia of Analytical Chemistry

fundamental optics that support both ATR and TIRF can be found in *Internal Reflection Spectroscopy*.[1]

2 THEORY OF ABSORPTION AND LUMINESCENCE

Absorption and luminescence are photophysical processes observed in both atomic and molecular systems. Since excitation of the chemical system by absorption is a prerequisite to any subsequent luminescence, we will begin with a discussion of optical absorbance. Also, the discussion will be limited to molecular systems.

2.1 Ultraviolet/Visible Absorption

The interaction of light with matter can be described by combining the classical and quantum theories of light with the quantum concepts of molecular structure. Light is a form of electromagnetic radiation and exhibits a well-known dual nature in that it behaves both as a classical wave and as a particle. The propagation of light is described as a wave phenomenon and is therefore characterized by a wavelength (λ) and a frequency (ν) which are related as shown in Equation (1)

$$\lambda = \frac{c}{\nu} \tag{1}$$

where c is the speed of light in a vacuum.

Three primary processes are possible whenever light impinges upon matter. The light can either be transmitted without loss, scattered or absorbed by the medium. The last case involves a transfer of energy to the medium composed of molecules characterized by their respective electronic energy configurations. When light is absorbed, the electronic configuration is altered and the molecule is promoted to a higher energy level. Each molecule possesses a series of discrete energy levels. To move from a lower energy level to a higher one, the molecule must absorb an integral quantum of light that is equal to the difference in the two molecular energy levels (Equation 2).

$$\Delta E = E_2 - E_1 \tag{2}$$

A quantum of light is called a ''photon'' and is described by Equation (3)

$$E = h\nu = \frac{hc}{\lambda} \tag{3}$$

where h is Planck's constant. Therefore, the electronic transitions associated with the absorption of light can be characterized by the wavelength of light absorbed. The energy necessary to produce electronic transitions in most molecules corresponds to the 200–800 nm wavelength region, or the UV (200–350 nm) and VIS (350–800 nm) ranges. Particular structural features that lead to absorption are called ''chromophores''. A more thorough discussion of structural effects on absorption can be found in the literature.[2]

2.2 Luminescence

Although there are numerous types of luminescence, for the purposes of this article we are primarily concerned with two: fluorescence and phosphorescence. Of these two, fluorescence is by far the most popular for analytical methodologies. The analytical sensitivity and selectivity of molecular fluorescence is confirmed by the number and diversity of analytical applications published each year.[3] Molecular fluorescence has proven especially valuable for the analysis of biological samples in which many of the molecules of interest exhibit fluorescence. The nature of fluorescence permits the examination of intracellular mechanisms and the detection of biologically active compounds present at very low concentrations.

The processes of molecular excitation and relaxation are illustrated graphically in Figure 1. The electronic energy levels represented by S_0, S_1 and S_2 are the ground, first excited and second excited singlet states, respectively. The excited triplet state is represented by T_1. A number of more closely spaced vibrational energy levels are associated with each electronic energy level. As shown in Equation (4), the excitation of a molecule to an excited singlet can occur owing to the absorption of a sufficiently energetic photon ($h\nu_a$, where h is Planck's constant and ν_a is the frequency of the absorbed photon).

$$S_0 + h\nu_a \longrightarrow S_1 \tag{4}$$

Excitation can originate from any of the ground state vibration levels. However, at room temperature most of the molecules populate the lowest vibrational level of the ground state. Therefore, the energy needed to promote a molecule to the S_1 state corresponds to the energy differences between the first vibrational level of S_0 and any of the various vibrational levels of S_1. This is a rapid process occurring within 10^{-15} s.

There are numerous mechanisms of relaxation available to excited-state molecules. They are often classified as either radiative or nonradiative depending on whether the excess energy is released as a photon or as some other form of energy. For most fluorescent molecules the various nonradiative processes generally combine to relax the excited state molecule down to the lowest vibrational level of S_1. Once the excited molecule relaxes to S_1, ν_0, the molecule can reach the ground state, S_0, by releasing a photon. This radiative transition between states of the same multiplicity is called fluorescence. Deexcitation to

Figure 1 Jablonski energy diagram.

any of the vibrational levels of S_0 is possible and usually occurs in 10^{-9}–10^{-6} s. This, of course, is not possible in molecules where a more competitive (faster) mechanism of relaxation is available. The direct excitation from the lowest vibrational level of S_0 to the lowest vibrational level of S_1 and the subsequent relaxation to the lowest vibrational level of S_0 is called the "0–0" transition. This transition is seldom observed except in the gaseous or crystalline state. In solution, the photon $h\nu_f$ (Equation 5) emitted as fluorescence is generally of longer wavelength (less energy) than the photon $h\nu_a$ which is absorbed (Equation 4).

$$S_1, \nu_0 \longrightarrow S_0, \nu_x + h\nu_f \tag{5}$$

Following fluorescence, further relaxation to S_0, ν_0 is possible by vibrational relaxation. The energy difference between the absorbed photon and the emitted photon is called the Stokes shift and is observed owing to the fact that fluorescence generally occurs from the lowest vibrational level of S_1 to some upper vibrational level of S_0. Furthermore, fluorophores can lose excitation energy owing to solvent effects in solution.

It is also possible for a molecule to undergo intersystem crossing from S_1 to T_1, provided that the respective vibrational levels of the two electronic states are energetically similar. Once this happens the molecule is free to relax to the lowest vibrational level of T_1. At this point, a radiative deactivation is once again competitive (Equation 6).

$$T_1, \nu_0 \longrightarrow S_0, \nu_x + h\nu_p \tag{6}$$

This is called phosphorescence and differs from fluorescence emission in two distinct ways. First, T_1 is generally lower in energy than S_1 so that phosphorescence emission is longer in wavelength than fluorescence. Also, since the occurrence of a radiative transition between states of different multiplicity has a low probability, the lifetime of phosphorescence (10^{-4}–10 s) is significantly longer than that of fluorescence. For this reason phosphorescence is more susceptible to quenching than fluorescence and is seldom observed in solution at room temperature.

3 ANALYTICAL INFORMATION

The total energy of the molecule is the sum of electronic, vibrational and rotational energies such that for each electronic state several vibrational and rotational sublevels are possible. This results in relatively broad absorbance spectra and minimal qualitative information content useful for sample identification purposes. However, quantitative applications are well documented based on the relationship commonly called Beer's Law (Equation 7).

$$A = -\log T = abc \tag{7}$$

In this equation, A is absorbance, T is transmittance, a is the absorptivity constant, b is optical pathlength, and c is sample concentration. Linear behavior is generally observed at concentrations below 0.01 M. Assuming a good absorber, a typical commercially available absorbance spectrophotometer can provide detection limits in the low nanomolar range. A typical commercial double-beam absorbance spectrophotometer is shown in Figure 2.

Figure 2 Double-beam absorbance spectrophotometer.

A detailed evaluation of the kinetics of fluorescence provides several analytically useful quantities that are necessary for the derivation of the quantitative aspects of the fluorescence measurement. Fluorescence is a first-order process with the rate of fluorescence depending on the concentration of excited molecules in S_1, as shown in Equation (8).

$$\frac{d(h\nu_f)}{dt} = k_f[S_1] \tag{8}$$

The rate of production of $[S_1]$ is equal to the rate of light absorption, I_a, as shown in Equation (9).

$$\frac{d[S_1]}{dt} = I_a \tag{9}$$

If illumination is maintained over several fluorescence lifetimes, a steady-state relationship between the rate of absorption, I_a, and the rate of fluorescence, $k_f([S_1])$, is achieved (Equation 10).

$$I_a = k_f[S_1] \tag{10}$$

However, Equation (10) is valid only in cases where there are no other processes competing with fluorescence for the deactivation of the excited state. A more realistic approach, shown in Equation (11), considers all of the possible relation processes.

$$I_a = (k_f + k_{IC} + k_{ISC} + k_Q[Q])([S_1]) \tag{11}$$

Each k represents the first-order rate constant for the respective processes described previously in Figure 1. If Equation (11) is rearranged and substituted for $[S_1]$ in Equation (8) it yields the relationship shown in Equation (12), in which the rate, or intensity, of fluorescence is equal to the rate of absorption multiplied by the quantum efficiency, ϕ_f.

$$I_f = \frac{d(h\nu)_f}{dt} = I_a\phi_f \tag{12}$$

The quantum efficiency, ϕ_f, is the ratio of the rate constant for fluorescence without any competition and with competition (Equation 13).

$$\phi_f = \frac{k_f}{k_f + k_{IC} + k_{ISC} + k_Q[Q]} \tag{13}$$

In simpler terms, ϕ_f is given by Equation (14).

$$\phi_f = \frac{\text{Number of photons emitted}}{\text{Number of photons absorbed}} \tag{14}$$

One divided by the denominator in Equation (13) is called the natural fluorescence lifetime, t, and is the time required for the fluorescence intensity to decay to 1/e times its initial value.

The preceding discussion (Equation 12) demonstrated that the intensity of fluorescence I_f is equal to the rate of absorption I_a multiplied by the fluorescence quantum efficiency ϕ_f. According to the Beer–Lambert law the amount of light absorbed by matter can be described by the differential Equation (15)

$$-\frac{dI}{dx} = kIc \tag{15}$$

where I is the intensity of light, x is the distance through the medium which it passes, k is a first-order rate constant and c is the concentration of the absorbing species. When this is integrated over a distance, b, the popular form of absorbance Equation (16) is produced.

$$A = \log(I_T I_0) = 2.3abc \tag{16}$$

In this form, A is the absorbance, I_T is the transmitted light, I_0 is the incident light, and a is the absorptivity. The amount of the incident light that is absorbed by the fluorescent sample is given by Equation (17).

$$I_T - I_0 = I_0 = I_0(1 - 10^{-2.3abc}) \tag{17}$$

This can be substituted for I_a in Equation (12) and expanded as a Taylor series to remove the exponential term. For dilute solutions in which the total absorbance is low (<0.01 AU), the Taylor expansion can be truncated. This produces a linear relationship between I_f and the fluorophore concentration c, as shown in Equation (18).

$$I_f = 2.3\, I_0\, \phi_f\, abc \tag{18}$$

At higher absorbances, the equation is no longer linear owing to a significant attenuation of the incident light as it passes through the sample.

The sensitivity of a given technique is defined as the amount of signal produced per unit concentration (or weight) of the sample. This is determined by the slope of a standard calibration curve. Equation (18) indicates the slope of a fluorescence calibration curve to be equal to $2.3\, I_0\, \phi_f\, ab$. Therefore, the sensitivity of the fluorescence measurement can be regulated by adjusting the intensity

Figure 3 Fluorescence spectrophotometer.

of the exciting light (I_0). This provides experimental versatility with fluorescence that is unavailable from absorption spectroscopy.

In the literature, sensitivity is often confused with detection limit. The detection limit is the minimum detectable quantity of an analyte. This value is more often determined by background interferences and detector noise levels than by the sensitivity. The low detection limits obtainable by fluorescence are well documented[4,5] in the literature and are often 1000 times below those of UV/VIS absorption. In fact, single molecule detection by fluorescence has been well documented in the literature and is now becoming somewhat routine.[6]

Fluorescence measurements are much more selective than most other analytical techniques. Since not all molecules fluoresce, the mere detection of fluorescence is selective. Also, since fluorescence generally originates from S_1, ν_0, the fluorescence spectrum of a pure one-component sample is independent of the excitation spectrum. No matter what excitation wavelength is selected, the shape of the emission spectrum will be the same. This fact provides the theoretical basis for the analysis of multicomponent samples. An optical diagram of a typical fluorescence spectrophotometer is shown in Figure 3.

4 FABRICATION OF THIN FILMS

4.1 Physical Deposition

The two main methods for producing thin, inorganic, surface coating films are vacuum sputtering and chemical vapor deposition (CVD). These techniques typically give reproducible high-quality films whose properties can be controlled within a certain range by variation of sputtering or chemical deposition parameters. Different modifications of vacuum sputtering and CVD are widely used in the optical industry to manufacture metal, metal oxide and metal halide coatings.

Thin polymer layers on solid supports are prepared by casting from polymer solution. Spinning of the substrate more often provides uniform thickness of the film. To manufacture large volumes of surface-supported films, the method of casting onto a linearly moving substrate is applied. To provide better adhesion of the polymer film, the substrate surface can be chemically modified. For example, simple treatment of glass with siloxanes dramatically enhances the adhesion of many polymers to originally hydrophilic glass surfaces.

Another powerful technique for thin organic layer preparation involves the Langmuir–Blodgett method of monolayer formation at the air–water interface. In principle, this technique can be applied for fabrication of thin films of a vast variety of organic compounds. However, the Langmuir–Blodgett method works better for amphiphilic molecules which comprise both hydrophilic and hydrophobic parts. Surface density and orientation of amphiphilic molecules can be controlled using a Langmuir–Blodgett balance. Since 1990, a renaissance of research on molecular organization stimulated the development of sophisticated Langmuir–Blodgett balances with capabilities of automated well-controlled deposition of organic monolayers and multilayers. A very complex multilayer molecular architecture of a sandwich type, which consists of a sequence of different compound monolayers, can be built at a solid surface.

4.2 Chemically Modified Surfaces

Surface chemistry is one of the parameters that determines the main features of the interfacial behavior of an adsorbate. The surface of a substrate can be modified by casting a thin polymer film, by vacuum deposition or CVD of an inorganic film, or by irreversible adsorption of macromolecules such as synthetic and natural biopolymers. Chemical modification of a thin monomolecular layer of a substrate is one of the most efficient ways to obtain a well-characterized solid surface with the desired properties. Numerous methods for chemical modification of inorganic and organic surfaces have been reported. This section describes selected methods of chemical modification of inorganic substrates such as glass, quartz and metal oxides, and focuses on procedures designed for covalent attachment of biological molecules.

Silane chemistry is one of the most widely used technologies to covalently attach a reactive group to the surface of an inorganic substrate. Different derivatives of trialkoxysilane compounds tipped with a variety of reactive groups are available commercially and can be used as coupling agents for covalent binding of proteins, DNA and other biomolecules of interest. These reagents bind to oxide surfaces via silane bonds. The opposite, free end of the silane reagent, that can carry such groups

as $-NH_2$, $-COOH$, or other reactive groups, is used to functionalize the surface by subsequent coupling of biomolecules. Triethoxysilanes are the most widely used compounds that react with the free hydroxyl groups of metal oxides by S_N2 exchange of the silane ethoxy groups for the silanol oxygen, with loss of ethanol. The reaction is catalyzed in the presence of a base. If the triethoxysilane derivative contains a primary amine group, the reaction is self-catalyzed, making external catalysis by a base unnecessary. In the catalyzed reaction, the base substitutes one ethoxy group of triethoxysilane, and a pentacoordinate silane intermediate is formed when a surface hydroxyl group replaces the base.

The purpose of the chemical modification is to obtain a monolayer or a submonolayer coating with active reactive sites at the tip of the attached molecule. However, in the case of the silanization, a multilayer silane film tends to occur instead of a mono- or submonolayer coating. This disadvantage can be avoided by proper selection of the silanization procedure. The silanization reaction dramatically depends on reaction conditions, and post-reaction ''curing''. Since the formation of siloxane bonds is possible between two surface-bound molecules (horizontal polymerization) and between triethoxysilane molecules in solution and at the surface, multilayer siloxane films tend to be obtained at excessive concentrations and time of reaction. A monolayer siloxane coating is formed during several minutes of exposure of a glass or silica surface to a trialkoxysilane solution in a dry solvent such as toluene or xylene at room temperature. Thus, a monolayer coating can be obtained by reducing the reaction time and/or concentration of the reagent.

Silanization procedures utilizing aqueous solutions of trialkoxysilanes have also been reported. However, these coatings typically exhibit poor stability, and functionalized coatings can be desorbed by washing. One reason for this behavior is related to the electrostatic interactions between oxide surfaces and triethoxysilane compounds containing amines. Since glass and silica surfaces are negatively charged over a wide pH range, aminated trialkoxysilane derivatives tend to be adsorbed owing to electrostatic interactions between positively charged amine groups and a negatively charged surface. Subsequent curing of the surface with an adsorbed amine derivative of triethoxysilane at 100–120 °C is required to stimulate transformation of the adsorbed compound to covalent binding via a silane bond. The functional activity of immobilized biomolecules depends on the chemistry and the length of spacer units between the triethoxysilane groups and the reactive group involved in the coupling of biomolecules. Relatively long spacer groups of 4–8 carbon atoms inserted between the reactive group ($-NH_2$, $-COOH$) and the surface-attaching triethoxysilane group allow better access of dissolved counterparts to the surface-attached functional group. In the case of short nonaliphatic spacers, surface-immobilized biomolecules frequently demonstrate reduction of their functional activity, which deteriorates significantly with storage time.

5 EXPERIMENTAL

5.1 Attenuated Total Reflectance

The total internal reflection (TIR) phenomenon can be explained with the aid of Figures 4 and 5. ATR is a term used with absorbance spectroscopy based on a common optical phenomenon called TIR. Application of TIR for ATR measurements has been most popular for vibrational absorbance with Fourier transform infrared (FTIR) spectroscopy. However, the fundamental principles are the same for ATR with the electronic absorbance applications of interest in this article. The principles of TIR were initially described by Newton in the early 18th century and are well documented in the more recent literature.[1,7,8] In brief, when a beam of light propagating within a medium of refractive index (η_1) encounters an interface with a medium of lower refractive index (η_2), it can undergo TIR for incidence angles (θ_i) greater than the critical angle (θ_c). Although the incident light totally reflects at the interface, a portion of the electromagnetic radiation penetrates the interface into the less dense medium. The intensity of this interfacial field, typically called the ''evanescent wave'', decays exponentially with distance from the interface (Equation 19).

$$\theta_c = \sin^{-1}\left(\frac{\eta_2}{\eta_1}\right. \tag{19}$$

The penetration depth (d_p) of the evanescent wave in the less dense medium is a function of incidence angle, refractive index ratio and incident light wavelength, λ_i (Equation 20). The penetration depth (pathlength) of the evanescent wave can be conveniently altered by changing incidence angles. The extremely short pathlength of the evanescent wave (in the order of the wavelength of light) excites a very small sample volume and thereby minimizes background absorption effects.

$$d_p = \frac{\lambda_i}{2\pi\eta_1\sqrt{\sin^2\Theta_i - (\eta_2/\eta_1)^2}} \tag{20}$$

Although light is efficiently propagated through the optical waveguide, the small proportion of energy present in the evanescent wave can be absorbed by surface components according to Beer's law. The total light loss in the waveguide is the sum of losses due to scattering from the bulk sample and surface, respectively, and from surface absorbance. With appropriate experimental

Figure 4 Conditions for internal reflection and refraction.

Figure 5 Graph of electric field amplitude and evanescent wave.

care,[9] the attenuation of the evanescent wave by absorbance can be accurately calibrated for a quantitative measure of components contained within the penetration depth of the evanescent field.

Figure 6 Generalized optical scheme for single and multiple reflection waveguides.

5.1.1 Instrumentation

It is difficult to describe any general instrumentation scheme for waveguide detection because it can take many different forms depending on the particular application (Figure 6). It has been properly noted that "the true genius behind waveguide detectors lies in the reagent chemistry and geometry".[10] However, in general, the typical ATR waveguide device must provide for multiple reflections owing to the relatively poor sensitivity of absorbance measurements with extremely short pathlengths. The exact number of reflections can vary from $<10\,cm^{-1}$ with planar slab waveguides to several thousand per centimeter with integrated optical waveguides (IOW). However, it should be noted that, to date, IOWs have not become popularly applied owing to fabrication problems, high scattering losses and fluorescence background problems.[11]

Associated instrumentation must provide for efficient optical coupling of light into the waveguide which is typically accomplished by either a prism or a grating coupler. Depending on the design of the waveguide, either broadband or monochromatic light can be used. Efficient detection in ATR also requires effective output coupling of the propagated beam into the appropriate detection device. Use of most of the common optical detectors (e.g. photodiodes, photomultiplier tubes, charge-coupled devices (CCDs)) has been reported in the literature in connection with ATR waveguide devices.

5.1.2 Applications

Initial applications of ATR for electronic spectroscopy of surfaces were primarily interested in increasing detection

sensitivity for surface adsorbates as compared with bulk transmission measurements. This was accomplished by use of multiple internal reflection waveguides which effectively increase the optical pathlength for the absorbance measurement while containing the optical beam parallel to the analytical surface. For example, Stephens and Bohn[9] observed better than a 1000-fold enhancement in the absorbance detection of a chemisorbed *p*-nitrobenzoic acid monolayer on a 150 μm glass waveguide compared with a traditional transmission experiment. They were also able to collect the absorbance spectrum of a 130 nm thick physisorbed film of phthalocyanine. Numerous other literature reports have cited similar sensitivity enhancements.

Closely paralleling those initial applications of ATR there appeared a large number of ATR-based sensor devices for various environmental and biological applications. For example, Yang and Saavedra[12] reported development of a sol–gel-derived planar IOW for Pb(II) and pH. The sol–gel layer served as a porous yet stable support for the indicator phase. The thin (<200 nm) sol–gel layer provided rapid response times. Several other similar sensors using various waveguide geometries have been reviewed by Dessy.[10]

Several reports of the combination of waveguide optics with electrochemical techniques have also appeared in the literature.[13–18] Dunphy et al.[13] demonstrated a 10^4 signal enhancement during the reduction of a submonolayer of surface-adsorbed methylene blue with a single-mode IOW coated with indium tin oxide as compared with a traditional transmission experiment. They estimated detectabilities of less than 1% of a monolayer for most cases. It has been noted that a fundamental problem that has limited popular use of IOW/ATR devices concerns the difficulty in detecting the broadband spectrum, since both the mode propagation angle and the coupling angle are functions of wavelength. Therefore, the IOW is typically only efficient over a narrow wavelength band. Mendes et al.[19] described a creative IOW design which combines a broadband Xe lamp with a prism input coupler and a series of two integrated gratings to compensate for wavelength dispersion in the IOW. A third output grating is then used to couple the dispersed ATR spectrum onto a CCD detector to provide simultaneous detection of the entire absorbance spectrum.

Some more recent reports[20,21] have described the use of IOW/ATR for measurement of absorption linear dichroism. The combination of absorption linear dichroism with emission anisotropy measurements allows molecular orientation of surface species to be determined. This is a difficult question to resolve but highly relevant to many areas of biotechnology. Edminston et al.[20] looked at the molecular orientation of cytochrome *c* on a variety of surface types, and Wood et al.[21] studied the orientation of site-directed immobilization of cytochrome *c* on thiol-based self-assembled monolayers.

5.2 Total Internal Reflection Fluorescence

Hirschfeld[22] first introduced TIRF in 1965, to examine solid/liquid interfaces. Since then many researchers have applied TIRF to examine various molecules at solid/solid, solid/liquid and liquid/liquid interfaces. TIRF is a surface-selective technique which is capable of detecting fluorescent probe molecules within a few hundred nanometers of the interface. The fluorescent probe molecules assist in investigating the interfacial chemical structure and environment. The probe molecules provide information about their surroundings by their spectral response, including spectral wavelength shifts, excited state lifetime and emission polarization.

TIRF spectroscopy has proven to be a very powerful and versatile technique for the study of surface and/or interfacial behavior of biological molecules and their aggregates.[23,24] TIRF has been successfully applied to numerous studies associated with solute adsorption, orientation and rotational mobility associated with conformational changes. Surface selectivity is achieved in TIRF by detecting only the evanescent-wave-excited fluorescence signals which originate within approximately the first 100 nm from the waveguide surface. This exceptionally short optical pathlength allows investigation of surface behavior even in the presence of highly concentrated solutions. In short, TIRF provides in situ, real-time, nondestructive, and highly sensitive detection suitable for studies on expensive biological materials available only in microliter quantities. Reliable detection of a few macromolecules per square micrometer has been documented with the utilization of commercial fluorescence spectrophotometers,[25] while custom-designed systems allowed single-molecule detection.[26]

The principles explained in section 5.1 for ATR apply equally to TIRF in respect to generation and behavior of the evanescent wave at the optically active surface. It is also important to understand the polarization properties of the evanescent wave, particularly for studies involving molecular orientation at the surface. The polarization properties of the transmitted field (evanescent wave) depend on the polarization properties of the incident light.[27] For instance, if the incident electric field is s-polarized its electric field vector is perpendicular to the plane of incidence and the transmitted field has the same polarization as the incident field. However, if the incident electric field is p-polarized its electric field vector lies in the plane of incidence and the transmitted field is elliptically polarized. As a result, the s-polarization case is amenable to fluorescence anisotropy measurements

of the interfacial region, whereas the p-polarization is considerably more complex. Additional properties of the evanescent wave and the underlying principles of TIRF are available in the literature.[1,27–29] The evanescent wave is primarily responsible for the electronic excitation of the fluorophore present in the lower refractive index medium. The intensity of the fluorescence excited (Equation 21) in the evanescent volume is the integrated product of the intensity of the evanescent wave and the fluorophore concentration (C_z).[28] In Equation (21), k_{ex} is a proportionality constant.

$$I_{ex} = k_{ex}\varepsilon\phi_f I_i \int_0^\infty C_z e^{-z/d_p}\, dz \qquad (21)$$

An important aspect of TIRF involves the reverse coupling of the emitted fluorescence back across the interface into the optical waveguide. The observed fluorescence depends on the observation angle (θ_o). By the principle of reciprocity, the effect of the observation angle on this reverse coupling is similar to the effect of the incidence angle on the evanescent wave penetration depth. Therefore, at θ_o greater than θ_{co} the fluorescence intensity contained in the evanescent observation volume can be described by Equation (22).

$$I_{em} = k_{em} \int_0^\infty e^{-z/d_p}\, dz \qquad (22)$$

θ_{co} differs from θ_c (Equation 19) owing to the dependence of the refractive index on the fluorescence wavelength, λ_f. In Equation (22), k_{em} is a proportionality constant and d_p is calculated using Equation (20) with λ_i and θ_i replaced by λ_f and θ_o, respectively. Subsequently, the TIRF intensity reaching the detector (for fixed $\theta_i > \theta_{ci}$ and fixed $\theta_o > \theta_{co}$) is the product of the two integrals in Equations (21) and (22) and can be represented by Equation (23), which is also referred to as a Laplace transform of the concentration–depth profile.

$$I_f = k_{ex}k_{em}\varepsilon\phi I_i \int_0^\infty C_z e^{-z/(d_{pi}+d_{po})}\, dz \qquad (23)$$

The TIRF signal can also be measured at a fixed observation angle for varying incidence angles which range from normal to grazing. Reciprocally, TIRF measurements can be made at a fixed incidence angle for varying observation angles which range from normal to grazing. (Both the incidence and observation angles are defined with respect to a normal to the interface.) This variable-angle technique is called variable-angle total internal reflection fluorescence (VATIRF). Generally, VATIRF data are represented as the variable-angle fluorescence intensity data curve. The data curve is a convolution of the fluorophore concentration–depth profile and the decaying evanescent wave. The complete concentration profile can be potentially extracted from the data by performing an inverse Laplace transform of Equation (23).

5.2.1 Instrumentation

Since the introduction of TIRF in the 1960s, waveguides and the associated instrumentation have generally been home-built and designed for specific applications. In 1995, the first general-purpose commercial TIRF cell was introduced. The design of the TIRF flow cell made the normally difficult TIRF experiment become routine. Figure 7 illustrates the basic optical design. The TIRF flow cell was prealigned for a specific commercial fluorometer and supplied with an easily assembled flow system to study kinetics of various surface interactions. This design provides high reproducibility of TIRF measurements by ensuring the exact positioning of optical elements against the excitation beam and emission axis. The TIRF cell differed from similar noncommercial TIRF cells

Figure 7 Commercial version of TIRF cell.

in the simple and fast assembly of the sandwich cell. The transparent gasket which forms the flow chamber (approx. 20 μl) and the transparent back plate facilitate easy visualization of the surface and allow acquisition of microscopic pictures by a long-focus objective.

The cell was equipped with a UV-quartz dovetail prism and optically coupled cover slide, as shown in Figure 7. The cover slide provides an easily interchangeable working surface and minimizes wear on the TIRF prism. Cover slides with hydrophilic, hydrophobic and electroconductive thin films, or specific soluble protein docking films could be obtained depending on the application. The TIRF cell could be used with most of the popular, commercially available research-grade spectrofluorometers.

5.2.2 Applications

Although an extensive review of these areas is beyond the scope of this article, the following sections will attempt to highlight some particular applications in the areas of protein adsorption, polymer adsorption, biosensors and chromatographic surfaces by way of example.

5.2.2.1 Protein Adsorption Using TIRF, protein adsorption at interfaces has been examined by intrinsic as well as extrinsic probes. External and internal standards have been used to quantitate the TIRF signal. Harrick and Leob[30] examined the adsorption of dansyl-labeled bovine serum albumin (BSA) onto sapphire and quartz surfaces. Adsorbed films were produced by immersing the internal reflection element (quartz or sapphire) into the solution of labeled protein. Multiple internal reflection elements with different geometries, a hemicylindrical prism and plates with 45° and 60° bevel angles with and without cavities, were used in the study. Van Wagenen et al.[31] used the intrinsic fluorescence of proteins to monitor the adsorption of unlabeled proteins on quartz surfaces. This intrinsic method avoids the need to label the protein thus eliminating the possibility of altering the physicochemical properties of the protein. Rockhold et al.[32] developed a quantitative method to determine the amount of protein adsorbed on hydrophilic glass and quartz surfaces. The protein adsorption studies were performed by measuring the intrinsic protein fluorescence as well as extrinsic fluorescence from fluorescein-labeled protein.

Hlady et al.[33–36] studied protein adsorption on non-gradient and gradient surfaces. They examined the adsorption of BSA and human immunoglobulin at non-gradient and gradient silica/electrolyte interfaces.[33,34] In a separate study they compared the adsorption of human high-density lipoproteins and low-density lipoproteins on hydrophilic and hydrophobic surfaces, respectively. The initial stage lipoprotein adsorption was of most interest. The adsorption of the two lipoproteins onto the two surfaces was found to be different. The lipoprotein adsorption on the hydrophilic surface was described quantitatively using a transport-limited adsorption model and assuming that the lipoprotein fluorescence quantum yield decreased upon adsorption.

TIRF spectroscopy was employed by Golander et al.[37] to quantify the adsorption of fluorescein-labeled lysozyme on bare mica and mica hydrophobized with a monolayer of 50% eicosyl amine ($C_{20}H_{41}NH_2$) and 50% eicosyl alcohol ($C_{20}H_{41}OH$). The steady-state binding of a fluorogenic lysozyme substrate to an adsorbed lysozyme layer, and subsequent steady-state enzymatic cleavage of the substrate were also quantitatively studied using a TIRF cell. The relative binding and cleavage rates were found to be larger on the hydrophobic mica than on the bare mica. Based on the lysozyme structure and on measurements of enzyme activity, possible models were proposed for the orientations of lysozyme on bare and hydrophobic mica.

Lok et al.[38] examined the adsorption of proteins (BSA) from flowing solutions on polymer (cross-linked polymethylsiloxane) films. The results of the study showed that at high solution concentrations, the evanescent-wave-excited bulk solution fluorescence and fluorescence excited by scattered light contributed a significant fraction of the total fluorescence signal. The contribution of surface-adsorbed protein to the total fluorescence was determined by exchanging the labeled protein solution in the flow cell with an unlabeled solution. The observed initial fast decrease in fluorescence intensity on exchange with unlabeled solution was attributed entirely to the displacement of bulk-solution-labeled protein, and not to the removal of loosely adsorbed protein.

TIRF spectroscopy cannot independently provide information about the exchange kinetics of adsorbed protein molecules in chemical equilibrium with the bulk protein solution. To access the kinetics of exchange, a combination of TIRF with fluorescence recovery after photobleaching (FPR) or fluorescence correlation spectroscopy (FCS) was introduced by Thompson et al.[39] A theoretical basis was developed for measuring equilibrium adsorption/desorption kinetics and surface diffusion of fluorescent-labeled solute molecules at solid surfaces. In the TIRF/FPR technique, adsorbed molecules are irreversibly photobleached by a flash from a totally internally reflected laser beam. Subsequent fluorescence recovery is monitored by an evanescent field, as bleached molecules exchange with unbleached molecules from solution and the surrounding nonilluminated regions of the surface. In the TIRF/FCS technique, the evanescent intensity is maintained at a constant and fairly dim level all through the experiment. The spontaneous fluorescence fluctuations due to individual molecules entering and leaving a

well-defined portion of the evanescent field are autocorrelated. Under appropriate experimental conditions, the rate constants and diffusion coefficient can be obtained from TIRF/FPR and TIRF/FCS curves.

Burghardt and Axelrod[40] applied the TIRF/FPR technique to study the dynamics of BSA adsorbed at a quartz glass/aqueous buffer interface. The technique allowed the measurements of desorption rates of rhodamine-labeled BSA and the detection of surface diffusion on a system in equilibrium without the need for any intrinsic spectroscopic change between the bound and unbound states. The data obtained revealed the presence of both irreversibly bound states and a multiplicity of reversibly bound states. The relative amount of reversible to irreversible adsorption was found to increase with increasing bulk protein concentration.

Burghardt and Axelrod[41] studied the conformational and dynamical properties of adsorbed proteins by combining TIRF with conventional fluorescence spectroscopic examination of singlet–singlet energy transfer and fluorescence polarization. They constructed a TIRF apparatus which easily fitted inside the sample chamber of a commercial spectrofluorometer. BSA was multiply labeled with two donor–acceptor pairs of 4-chloro-7-nitro-2,1,3-benzoxadiazole–rhodamine and dansyl–eosin. The labeled BSA molecules were adsorbed at a quartz glass/aqueous buffer interface. The adsorbed protein was in equilibrium with the bulk solution. The spectral data exhibited significantly less effective singlet–singlet transfer from the donor to the acceptor in surface-adsorbed BSA relative to bulk-solution-dissolved BSA. With certain assumptions, this energy transfer change was interpreted as a conformational change of BSA upon adsorption.

Morrison and Weber[42] employed TIRF polarization measurements to selectively examine fluorescent molecules adsorbed to the interface region between two immiscible liquids. A fluorescent compound bis-ANS (4,4′-bis-1-phenylamino-8-naphthalenesulfonate), was examined at a decalin/water interface. The adsorbed fluorophore displayed an apparently hindered rotation in the plane of the interface with rotational diffusion coefficients 3- to 12-fold lower than that expected for bis-ANS in solution. As a better approximation of a biological membrane, bis-ANS binding to the decalin/water interface was examined in the presence of a nonfluorescent surfactant, cetyltrimethylammonium bromide (CTAB). The addition of CTAB increased the affinity of bis-ANS for the interface. Also the addition of BSA was found to cause desorption of bis-ANS from the interface owing to competitive binding.

5.2.2.2 Polymer Adsorption Masuhara et al.[43] examined the interfacial characteristics of a polymer film on a sapphire substrate by time-resolved TIRF spectroscopy. In the study polystyrene films were doped with fluorescent *p*-bis(2-(5-phenylene-oxazolyl)benzene). Fluorescent decay curves were investigated as a function of incident angle. Monitoring the fluorescence helped to elucidate the photophysical processes and molecular motions in the nanosecond to picosecond time domains. As a further improvement of the technique, Itaya et al. performed the TIRF measurement under a microscope.[44] This enabled them to obtain time- and space-resolved data on fluorescence characteristics.

Itaya et al.[45] studied poly(methyl methacrylate) (PMMA) films doped with pyrene by TIRF. They examined the distribution of the dopant molecules in the polymer film and the microenvironment around the dopant molecules. The results were compared with fluorescence data obtained under normal excitation conditions. In these studies sapphire was used as an internal reflection element. Polymer films were both cast and film-coated onto the sapphire substrate. The concentration of the dopant molecule (pyrene) was varied in the experiments. The results indicated that micropolarity around pyrene molecules located at or near the sapphire/polymer film interface was higher than the bulk. Based on the pyrene monomer and excimer fluorescence data they concluded that the aggregate state of pyrene was significantly different at the interface and the bulk.

5.2.2.3 Biosensors The development of convenient surface chemistries suitable for the attachment of biospecific molecules to waveguide surfaces has provided tremendous opportunities for the design of very sensitive and selective biosensor devices. The development and optimization of such devices is highly dependent on a thorough understanding of the molecular dynamics at the surface or interface. Both steady-state and lifetime-based TIRF techniques have been very useful for investigation of surface and interfacial behavior. An excellent review[46] of lifetime-based TIRF applications for biosensors appeared in 1997.

Most of the biosensor development activity so far has centered on immunoassay reaction chemistries due to their inherent biospecificity and commercial availability. A large number and variety of TIRF biosensors has been reported. A thorough review[47] appeared in 1991. Plowman et al.[48] were the first to demonstrate femtomolar sensitivity for a model immunoassay system. This system consisted of a dual channel, 1-μm thick, siliconoxynitride IOW deposited on a 10-cm quartz wafer. A He–Ne laser was used for excitation and the emitted fluorescence was dispersed with a single grating spectrograph onto a CCD camera for simultaneous detection of both channels. This arrangement conveniently provided comparable sample

and reference spectra. More channels could be added for multianalyte applications.

One problem associated with TIRF biosensors is that a sensor with adequate sensitivity generally requires a biospecific interaction with high binding affinity. The affinity constants for most antibody–antigen interactions are determined largely by the dissociation constants, k_d, with little variation observed in rates of association. Additionally, surface immobilization typically results in a reduced k_d. In this case, the sensor binds the analyte kinetically, irreversibly preventing response to changes in analyte concentration and reuse. Regeneration of the sensor surface is difficult at best. On the other hand, a higher dissociation rate, which would lend itself to a linear and reusable sensor, results in lower affinity and poor sensitivity. Consequently, most biosensors are disposable devices and quantitation is obtained using multiple single-use sensors. Recently, a new reusable biosensor platform which provides simultaneous fluorescence detection and electrochemical control of biospecific binding has been developed.[25] Biotin was covalently attached to a transparent indium tin oxide electrode, which also served as an integral part of a TIRF flow cell. TIRF was used to monitor biospecific interactions while electrochemical polarization was employed to control the interactions. Antibody–antigen and avidin–biotin interactions both exhibited reversibility over 30 reuse cycles. A generalized TIRF biosensor scheme known as a ''sensogram'' is shown in Figure 8.

5.2.2.4 Chromatographic Surfaces The application of TIRF has been further expanded for the characterization of chromatographic surfaces to obtain a better understanding of the solute separation mechanism on a molecular level. The microenvironment polarity of chromatographic surfaces has been investigated by TIRF.[49,50] Hartner et al.[49] derivatized a fused silica plate with octadecyltrichlorosilane to obtain a C_{18} surface layer. The derivatized plate was optically coupled, with an index matching fluid, to an internal reflection quartz prism. Rangnekar and Oldham[50] chemically modified a multiple internal reflection element (single-pass parallelepiped 60° bevel angle UV-quartz plate) with octadecylchlorosilane and AquaSil™. Their TIRF optical configuration provided multiple internal reflections (number of reflections = 7) which increased the sensitivity. In both studies, the interfacial molecular environment was probed by pyrene physisorbed onto the modified surface. Pyrene TIRF emission spectra were collected in the presence of overlaying methanol/water mixtures. TIRF provided sufficient selectivity and sensitivity to allow the environment of the interface to be probed by pyrene which was adsorbed from the bulk solution. The percentage of the TIRF signal from the surface-adsorbed pyrene and the bulk-solution pyrene depends on the partition ratio under the conditions and the depth of penetration of the evanescent wave beyond the interface. The vibronic band intensities of pyrene, which are quite sensitive to the surrounding polarity, provided an insight to the polarity of the interior of the C_{18} chains and the chain configuration in the presence of different polar solvents.

TIRF anisotropy measurements have led to estimations of the microviscosity of the chromatographic stationary phase[51] and the orientational dynamics of solutes in a chromatographic stationary phase.[52,53] The basis of fluorescence anisotropy measurements is that,

Figure 8 Generalized sensogram for a TIRF biosensor.

upon excitation of the sample with polarized light, the polarization of the emission intensity is related to the molecular orientation. Since the molecule rotates within its excited state lifetime, the emitted fluorescence is depolarized. The fluorescence depolarization (or anisotropy) measurements disclose information concerning rotational mobility, which in turn is associated with the size and shape of the fluorophore and the viscosity of the surrounding medium.

Rangnekar et al.[51] chemically modified a UV-quartz surface with different silylating reagents to obtain either C_1-, C_3-, C_8- or C_{18}-modified silica surfaces. TIRF anisotropy data of 1,6-diphenyl-hexatriene were collected on unmodified and modified surfaces in the presence of overlaying solvents covering a range of viscosities. Their results indicate that the adsorption and partitioning mechanisms depend at least partially on the carbon number of the alkyl chain. They estimated the C_{18} surface microviscosity to be approximately 18 cP.

Wirth and Burbage[52] have derived mathematical relationships for TIRF anisotropy studies of adsorbate reorientation at surface/liquid interfaces. The group examined the reorientation of acridine orange adsorbed on an (octadecylsilyl)silica surface. In the study, an octadecylsilane (ODS)-derivatized fused silica plate was optically coupled, with a silica index matching fluid, to a trapezoidal internal reflection prism. The thermodynamic equilibrium between the surface-adsorbed acridine orange and aqueous acridine orange was maintained by continuously flowing the solution through a flow cell. The surface acridine orange was excited with light polarized either in-plane or out-of-plane by using an evanescent wave. Fluorescence-domain spectroscopy was used to characterize the fluorescence anisotropy decays of acridine orange. The experiments revealed that the out-of-plane rotations of acridine orange at the ODS/water interface were strongly hindered, while the in-plane rotations gave rise to a double exponential decay of unknown origin. The interpretation was that acridine orange resides at the ODS/water interface. Wirth's group[53] has also examined the effect of wetting by alcohols on the orientations of C_{18} chains. The geometry of the probe solute bis-*p*-(*o*-methyl)styrylbenzene used in the study favored preferential alignment with the C_{18} chains. It was assumed that any changes in the orientational distribution and dynamics of the C_{18} chains caused related changes in the orientational distribution and dynamics of the probe solute. The results indicate that the C_{18} chains lie flat on the surface when water is the mobile phase. A small amount of alcohol added to the water causes the C_{18} chains to become extended towards the surface normal and the chains become random in orientation. But it is likely that wetting has a significantly smaller effect upon the chain orientation.

This article is a survey of the data analysis methods that have been applied to ultraviolet (UV) and visible molecular absorbance and fluorescence measurements. The section after the Introduction reviews the principles of the most widely used types of absorbance and fluorescence measurements. These include steady-state, dynamic and multidimensional measurements. After a brief description of absorption and fluorescence instruments, three classes of data analysis methods for molecular absorbance and fluorescence are described: regression methods, decay analysis and matrix factorization methods. Result validation, software alternatives and future developments are discussed in short sections at the end of the article. A short matrix algebra primer is provided as an appendix to the article.

1 INTRODUCTION

Ultraviolet/visible (UV/VIS) molecular absorbance measurements are among the most widely used spectrochemical methods because they provide nearly universal detection and require modest investments in equipment and user training, except in the case of ultrafast dynamic measurements. UV/VIS molecular fluorescence measurements are less widely used than absorbance methods; relatively few molecules are intrinsically good fluorescers and equipment, maintenance and training for dynamic experiments can be expensive. Despite this, fluorescence measurements are critical in several areas of important research. First, the detection limits of fluorescence are unparalleled by any other method for molecules in solution. Single molecule studies routinely capitalize on this feature.[1,2] Second, fluorescence emission occurs on the timescale of molecular motions and is thus sensitive to molecular interactions and dynamics.[3] Dynamic fluorescence measurements can be used to measure excited state reaction rates,[4,5] translational[6] and rotational diffusion coefficients,[7] intramolecular distances, solute–solvent interactions and related parameters.[8] Several fluorophores emit microenvironment sensitive fluorescence which can be correlated to local solvent properties such as polarity, viscosity, pH,[9] and potential.[10] These capabilities are the basis of the wide use of fluorescence methods in photochemical, biophysical, and photobiological studies. (Of course, this feature has a dark side. It is a primary source of fluorescence sensitivity

to matrix effects.) Third, fluorescence is a function of many experimental variables.[11] Experimental variables can be adjusted to avoid known interference or the fluorescence measurement can be made as a function of simultaneous variation in several variables in order to take advantage of numerical methods for analysis in the presence of interference.[12]

This article is a survey of the data analysis methods that have been applied to UV/VIS molecular absorbance and fluorescence measurements. While the name of this Series implies an exhaustive reference that includes the most obscure data analysis procedures, this report is limited to methods that are in wide use or enable analysts to take advantage of advances in instrument technology. Most of the material is presented in two of the seven report sections. The first, section 2, reviews the principles of the most widely used types of absorbance and fluorescence measurements. This section introduces mathematical expressions that describe the data acquired in each type of measurement for which analysis methods will be discussed. These expressions are important because they define the information content of each measurement and provide the basis for deciding which analysis procedure(s) is (are) best suited to recovering the desired information from the data. The reviews also provide brief overviews of the potential applications of each measurement. The second major section is section 4, which organizes data analysis methods for molecular absorbance and fluorescence into three classes. Section 4 also describes the principles and application of the most prominent data analysis methods in each of the three classes. Section 5 is the discussion of result validation for the various analysis classes. It is not as large as sections 2 and 4, but the topic is very important. Despite the best efforts of generations of scientists and statisticians, there is generally an element of subjectivity in data analysis. This is particularly true of measurements comprised of combinations of exponentials, such as dynamic absorbance and fluorescence. It is imperative that data analysis results be evaluated for statistical relevance and stability and bound by confidence intervals whenever possible.

Even the simplest measurement, for example a single sample absorbance and the absorbances of the calibration standards, can be organized into a data set using matrix algebra. Topics such as multicomponent analysis, multichannel (multiple variable) measurements, and curve fitting which involve more complicated data arrangements and operations, would be impossible to discuss without matrix algebra. There are many good tutorials on matrix algebra that will help the reader master the algebra used in this article.[13] The most important ideas to remember are: (1) addition, subtraction and scalar multiplication for vectors and matrices are directly analogous to their scalar counterparts; (2) multiplying by an inverse matrix is analogous to division; (3) most single variable operations, for example differentiation, integration, expansion, have direct analogies to vectors and matrices.

A detailed description of the notation used in this report is given at the beginning of the matrix algebra basics in Appendix 1. It suffices here to say that conventional matrix notation and variable names are used wherever possible. For example, boldface Roman and Greek letters represent matrices and vectors. Unfortunately, a uniform and consistent notation scheme is incompatible with some commonly used variable names. For example, the capitalized variable I typically represents light intensity, a scalar quantity. In this article, underlining and italics will distinguish scalar variables and vectors. For example, the intensity of fluorescence is represented by the italicized variable I_f; a single underline under an italicized variable indicates a related vector quantity, $\underline{I_f}$; and a matrix is indicated by double underlining, $\underline{\underline{I_f}}$. (It is important to remember that a series of italicized variables and their unitalicized counterparts, e.g. S, $\underline{S}$, $\underline{\underline{S}}$ and s, **s**, **S**, are unrelated.) In section 2, boldface also will be applied to the independent variables to help emphasize the order of the measurement. So, $I_f(\lambda_{ex}, \lambda_{em}, \varphi_{ex}, t)$ or I_f is a single value: the intensity observed after excitation at λ_{ex} at one λ_{em} through polarizer set to angle φ_{ex} at t seconds after excitation. $\underline{I_f}(\boldsymbol{\lambda}_{ex}, \boldsymbol{\lambda}_{em}, \varphi_{ex}, t)$ or $\underline{I_f}(\boldsymbol{\lambda}_{ex})$ is a vector: the fluorescence emission spectrum produced by excitation at λ_{ex}, observed through polarizer set at φ_{ex} at time t after excitation. $\underline{\underline{I_f}}(\lambda_{ex}, \boldsymbol{\lambda}_{em}, \varphi_{ex}, \mathbf{t})$ or $\underline{\underline{I_f}}(\boldsymbol{\lambda}_{em}, \mathbf{t})$ is a matrix: the fluorescence intensity produced by excitation at λ_{ex}, monitored as a function of λ_{em} and t through a polarizer set at φ_{ex}. This can go on, but I hope the point is made. Data dispersed in more than three dimensions and N-way matrices are germane to the topic, but the requisite data analysis methods are beyond the scope of this article. There is only a brief discussion of three-way fluorescence data in section 4.4.3. The other cases of unconventional notation arise when a single variable name is commonly used to define two entities. Some common variable names have been changed in order to avoid multiple definitions for variables wherever possible. For example, the variable r commonly represents both the distance between donor–acceptor pairs in energy transfer measurements and the fluorescence anisotropy. In this article, d denotes the interatomic distance to distinguish it from the fluorescence anisotropy. Despite these steps, multiple variable definitions could not be completely avoided. The most glaring example is the use of the letters i, j, k, l, m, n, p and q to represent element labels in vectors and matrices and counters in sums and products in addition to their use as variables.

2 PRINCIPLES OF ULTRAVIOLET/VISIBLE MOLECULAR ABSORBANCE AND FLUORESCENCE MEASUREMENTS

2.1 Ultraviolet/Visible Absorbance Data

2.1.1 Steady-state Ultraviolet/Visible Absorbance Data

The energy level spacing of many molecules, especially large organic molecules, is such that they absorb light in the UV to visible wavelength range, that is ~200–800 nm. This is illustrated in the Jablonski diagram depicted in Figure 1. The intensity of light absorbed by a sample is an extensive property that depends on the electronic energy level spacing in the chromophore and the number of chromophores the light beam encounters. Specifically, Beer–Lambert's law relates the intensity of light absorbed to the concentration of solution species, as shown in Equations (1) and (2):

$$I_T(\lambda_{ex}) = I_I(\lambda_{ex})e^{-\varepsilon(\lambda_{ex})bc} \quad (1)$$

$$A(\lambda_{ex}) = \log\frac{I_I(\lambda_{ex})}{I_T(\lambda_{ex})} = \varepsilon(\lambda_{ex})bc \quad (2)$$

where I_I is the incident light intensity, I_T is the transmitted light intensity, $\varepsilon(\lambda_{ex})$ is the molar absorptivity at a specific wavelength, b is the beam pathlength through the sample, c is the concentration of the chromophore and A is the absorbance. The absorbance spectrum, $\underline{A}(\boldsymbol{\lambda}_{ex})$, is a plot of the absorbance as a function of excitation wavelength. The absorption wavelength reflects the energy of the excited state. The spectrum band structure reflects the vibronic band spacing of the chromophore excited state. Figure 2 depicts the absorbance spectra of two forms of phytochrome, a photoreceptor that regulates plant growth and development.[14] The biologically active far-red-light absorbing form is reversibly photogenerated from the red-light absorbing form.

Figure 1 Jablonski energy level diagram. S_0, ground state singlet; S_1, excited singlet state; T_1, excited triplet state; λ_1–λ_4, wavelength ranges; IC, internal conversion; VR, vibrational relaxation; ISC, intersystem crossing; EC, external conversion.

Figure 2 Steady-state absorbance spectrum of the red-light and far-red-light absorbing phytochrome in 10 mM phosphate buffer, pH 7.8 at 278 K. (Reproduced by permission of the American Chemical Society from Bischoff et al.[14])

As a consequence of Beer's law, the majority of absorbance data is acquired as an indicator of concentration. Hence, the goal of most absorbance data analysis is to use the dependence of the absorbance on the analyte concentration for quantitation. UV/VIS molecular absorbance spectra of molecules in liquid solution near room temperature are typically broad. Spectral overlap, absorption by other sample components and matrix effects that produce deviations from Beer's law all complicate quantitation.

2.1.2 Dynamic Ultraviolet/Visible Absorbance Data

Several experimental procedures generate dynamic absorbance data. As in the case of steady-state data, the goal of such analyses is to quantify the components of a system, but with respect to time. These experiments monitor reaction progress, so the goal of the data analysis is isolation of individual component spectra and evaluation of system kinetics. Kinetic analysis generally consists of identifying a model that describes the reaction and determining the rates of the various processes that occur within the system.

In the simplest versions of these experiments, absorbances at a single wavelength are measured as a function of time. Absorbance spectrometers based on multichannel detectors are available commercially at modest prices, making spectra measured as a function of time a common alternative data format.[15] Multichannel spectrometers can be used to monitor chromatographic and electrophoretic separations or, more commonly, to study kinetic behavior. The mixing apparatus, source pulse rate and detector rise time define the measurement timescale.

A spectrometer based on a deuterium lamp and photodiode array can monitor reactions exhibiting millisecond or slower kinetics. Stopped-flow methods, xenon-flash lamps and intensified photodiode arrays can monitor microsecond kinetics. Pulsed-laser techniques such as differential transient absorption can monitor the time-dependent behavior of faster processes. For instance, picosecond dynamics can be monitored by measuring the difference in the absorbance of the unexcited sample and the sample at some time after excitation by a pump laser pulse.[16] Monitoring this difference as a function of the delay between the pump beam and probe beam produces a record of the changes in the absorption as a function of time on the scale of the delay. Figure 3 depicts the transient absorption spectra of the visual pigment rhodopsin.

In multichannel kinetic measurements, the data set acquired is an absorbance–time matrix. Beer's law defines the components of this matrix. Assuming unit pathlength, the matrix elements are the sums of the products of the molar absorptivities of the sample components at the observed wavelengths and concentrations of the components at the observation times, as shown in Equation (3).

$$\underline{\underline{A}} = \sum_{k}^{K} \boldsymbol{\varepsilon}_{\cdot k} c_{\cdot k}^{\mathrm{T}} = \mathbf{E}\mathbf{C}^{\mathrm{T}} \tag{3}$$

Each column of $\underline{\underline{A}}$ is the absorbance spectrum of the sample at a single observation time. Each row is the time course of the absorbance at a single wavelength. Each column of **E** consists of the molar absorptivities of one sample constituent at all the wavelengths monitored during the measurement. Each column of **C** stores the ground-state concentrations of one sample constituent as a function of the observation times. In the case of transient absorbance measurements, the columns of **C** are the excited-state concentration profiles. The goal of kinetic analysis is to isolate the time profiles of the sample constituents, **C**, and determine the kinetic rates that describe the time dependence of the concentrations.

Figure 3 Transient differential absorption spectra of rhodopsin at various probe delays (~10 fs probe) following a 35 fs pump pulse at 500 nm. (Reproduced by permission of Blackwell Science from Mathies.[16])

2.2 Fluorescence Intensity Measurements

2.2.1 Steady-state Intensity Measurements

When rigid molecules that have extended conjugated π-electron systems are photoexcited, many of the vibrational and rotational deactivation mechanisms that depopulate excited states are not available. Such molecules relax via photon emission. In conjugated organic molecules, fluorescence is usually observed during transitions from the first excited to ground singlet states, as depicted by bold solid lines in Figure 1.

The intensity of fluorescence emission is a function of several measurement variables and conditions; the most crucial are the excitation source properties. First, the wavelength of the excitation must correspond to the electronic energy level spacing of the fluorophore (Figure 1) in order to produce the excited state. Fluorescence emission is a random process that is driven by photoexcitation. A differential equation describes the rate of fluorophore excitation and relaxation characterizing the time dependence of the number of excited states in a homogeneous population of fluorophores, as shown in Equation (4)

$$\frac{\mathrm{dz}}{\mathrm{dt}} = \mathrm{e} - \mathrm{k_f z} \tag{4}$$

where z represents the instantaneous concentration of excited fluorophores, e is the rate of excitation, and $\mathrm{k_f}$ is the first-order rate constant describing excited state deactivation. The relaxation rate is actually a combination of the rates of all processes that deactivate the excited state, $\mathrm{k_f} = \mathrm{k_f^0} + \mathrm{k_{nr}}$ where the nonradiative processes (see Figure 1) have been collected into a single term, $\mathrm{k_{nr}}$. The

time dependence of the emission also depends on the time course of the excitation beam, $\mathbf{e} = \mathbf{I}_I(\lambda_{ex}, \mathbf{t})$. The observed intensity is the convolution of the excitation beam and the impulse response, i.e. system response to excitation by an infinitely narrow pulse. In the case of single fluorophores in dilute isotropic solution the impulse response function is generally a monoexponential decay. Equation (5) shows:

$$I_f(\lambda_{ex}, \lambda_{em}, \mathbf{t}) = k_f V \mathbf{z} = k_f V[I_I(\lambda_{ex}, \mathbf{t}) \circ z_0(\lambda_{ex}, \lambda_{em})\, e^{-\mathbf{t}/\tau_f}] \quad (5)$$

[where V is the volume of solution from which fluorescence is collected, $\circ$ denotes convolution, and $z_0(\lambda_{ex}, \lambda_{em})$ is the initial ($t = 0$) excited state concentration.] The decay constant in the impulse response is the inverse of the average lifetime of a fluorophore in the excited state, τ_f. It is the time required for the excited state population to decrease by 63%.

In steady-state measurements, the excitation function is constant, $\mathbf{e}(\mathbf{t}) = I_I(\mathbf{t})k_A c$. The ground state fluorophore concentration, c, is unchanged by the production of excited states at rate k_A. The constant (except for noise) source intensity produces a steady pool of excited fluorophores. The number of excited fluorophores reaches a constant value as a dynamic equilibrium between excited state production and deactivation is reached. The solution of Equation (4), shown in Equation (6), in this case is proportional to

$$z(\mathbf{t}) = \frac{k_A c}{k_f + k_{nr}} \quad (6)$$

Another expression for the steady-state fluorescence can be derived from the intensity of the light absorbed by the molecule, as shown in Equation (7)

$$I_A = I_I - I_T = I_I(1 - e^{-\varepsilon bc}) \quad (7)$$

The fluorescence quantum yield, ϕ_f, is the number of photons emitted per photon absorbed. Equation (8) shows:

$$I_f(\lambda_{ex}) = \phi_f I_A(\lambda_{ex}) \approx 2.303 \phi_f I_I(\lambda_{ex}) \varepsilon(\lambda_{ex}) bc \quad (8)$$

The intensity of fluorescence, I_f, is proportional to the incident light intensity at low absorbances ($A < 0.050$). The excitation spectrum $\underline{I_f}(\boldsymbol{\lambda}_{ex})$ illustrates the dependence of the emission intensity on excitation wavelength. The excitation spectrum has the same profile as the absorbance spectrum when it is corrected for instrument response and measurement conditions, yet it is measured at concentrations well below the detection limits of absorption spectrometers. The excitation spectrum of perylene is pictured in Figure 4.

The steady-state fluorescence intensity is a function of several measurement parameters other than the source intensity and excitation wavelength, λ_{ex}. These include the emission wavelength λ_{em}, excitation light polarization φ_{ex} and quencher or energy transfer acceptor concentration, [Q] or [A]. The emission wavelength dependence of the fluorescence intensity is given by Equation (9)

$$I_f(\lambda_{em}) = \phi_f I_I(\lambda_{ex}) \varepsilon(\lambda_{ex}) \zeta(\lambda_{em}) bc \quad (9)$$

where ζ is the probability that a photon will be emitted at a specific wavelength and the other variable designations are the same as in Equation (8). The emission spectrum is a record of the wavelength dependence of the fluorescence intensity. The emission spectrum of perylene is shown in Figure 5. The symmetry between the perylene excitation and emission spectra is observed in the spectra of many fluorophores. It is attributed to similarities in the energy level spacing and transition probabilities in the ground and excited states (the Mirror Image law).

As Figures 4 and 5 illustrate, fluorescence excitation and emission spectra of molecules in solution are quite broad. Bandwidths over 50 nm are common.

Figure 4 Uncorrected fluorescence excitation spectrum of perylene in ethanol monitored at 437 nm.

Figure 5 Uncorrected fluorescence emission spectrum of perylene in ethanol excited at 415 nm.

Figure 6 Fluorescence emission spectra (excitation wavelength fixed at 335 nm) and fluorescence synchronous spectra (excitation wavelength scanned from 300 nm to 475 nm) of an anthracene/perylene mixture in ethanol.

Consequently, spectral overlap is a primary limitation to accurate fluorescence analysis of multicomponent samples. In synchronous spectra, the fluorescence intensity is monitored as both the excitation and emission wavelength (monochromator) settings are changed.[17] The resulting spectra can have reduced bandwidths and improved selectivity, as the synchronous spectrum in Figure 6 illustrates. Derivative spectra[18] can also exhibit narrowed bandwidths. However, the resolution enhancement can be offset by the concomitant decrease in the signal-to-noise ratio.

As in the case of absorbance measurements, analyte quantitation is the goal of most steady-state fluorescence intensity analysis. When the species of interest is not intrinsically fluorescent, fluorescent groups can be attached covalently or noncovalently, then used to locate and/or quantitate the analyte. In most routine analyses, the analyte concentration is proportional to a single fluorescence intensity value. The ratio of the fluorescence measured at two wavelengths also can be correlated to analyte concentration.[19] This approach is not as widely used as the single channel method, but has the additional benefit of reducing measurement vulnerability to source fluctuations and matrix effects. Calibration and quantitation using the entire excitation or emission spectrum, which can permit simultaneous multicomponent analysis and contaminant detection, is gaining acceptance but is not widely practiced.[12,20]

2.2.2 Time-resolved Intensity Measurements

The kinetics of photoinduced processes monitor dynamic processes that occur on the timescale of the fluorophore lifetime or the effect of the solvent on fluorophore dynamic properties. Probe methods are widely used to characterize macromolecules such as surfactants, polymers,[9] proteins,[21] nucleic acids[22] and lipids.[23]

In time-correlated single photon counting[24] and other time-resolved emission decay measurements, the emission intensity observed at the detector is the convolution of the excitation pulse and impulse response, as shown in

Figure 7 Time-resolved emission decay of 2,6-toludinylnaphthalene sulfonate in phospholipid vesicles: (a) excitation profile; (b) emission decay; (c) simulated decay; (d) residuals. (Reproduced by permission of the Biophysical Society from Easter et al.[25])

Equation (10)

$$I_f(\lambda_{ex}, \lambda_{em}, \mathbf{t}) = k_f V[I_I(\lambda_{ex}, \mathbf{t}) \circ z_0(\lambda_{ex})\zeta(\lambda_{em})\, e^{-\mathbf{t}/\tau_f}] = k_f V \sum_s I_I(\lambda_{ex}, s) z_0(\lambda_{ex})\zeta(\lambda_{em})\, e^{-(\mathbf{t}-s)/\tau_f} \quad (10)$$

where z_0 now equals 2.303 A (λ_{ex}). Figure 7 illustrates the time-dependence of 2,6-toludinylnaphthalene sulfonate in phospholipid vesicles after pulsed excitation.[25]

2.2.3 Frequency-domain Intensity Measurements

The frequency-domain intensity decay measurement produces the Fourier transform of the time-domain measurement using a sinusoidally modulated excitation beam.[26] The signal observed at the detector in a frequency-domain measurement of a single fluorophore in ideal solution is the convolution of the impulse response and excitation function. Specifically, Equation (11) shows

$$\underline{I_f}(\lambda_{ex}, \lambda_{em}, \mathbf{t}) = k_f V[(I_I(\lambda_{ex}) + p_{ex} \sin w\mathbf{t}) \times \circ\, z_0(\lambda_{ex})\zeta(\lambda_{em})\, e^{-\mathbf{t}/\tau_f}] = \overline{I_f}(\lambda_{ex}, \lambda_{em}) + p_{em} \sin w\mathrm{t} + q_{em} \cos w\mathrm{t} = \overline{I_f}(\lambda_{ex}, \lambda_{em})[1 + m_{em} \sin(w\mathrm{t} - \varphi_{em})] \quad (11)$$

at each frequency, w. The emission oscillates at frequency w, but is demodulated and lags behind the oscillating excitation beam (Figure 8a). The phase lag, φ_{em}, and relative modulation, m_{em}/m_{ex}, of the emission at several frequencies can be related to the impulse response through the Fourier transform. Equation (12) shows

$$\mathbf{z}(t) = z_0(\lambda_{ex})\zeta(\lambda_{em})\, e^{-\mathbf{t}/\tau_f} \Longleftrightarrow z_0(\lambda_{ex})\zeta(\lambda_{em}) \times \frac{1/\tau - iw}{1/\tau^2 + w^2} = z_0(\lambda_{ex})\zeta(\lambda_{em}) m_{em}\, e^{-i\boldsymbol{\varphi}_{em}} = \mathbf{q} + i\mathbf{p} = \tilde{\mathbf{z}}(w) \quad (12)$$

The vectors $\boldsymbol{\varphi}_{em}$ and $\mathbf{m}_{em}$ represent, respectively, the phase lags and demodulation factors of the decay at the excitation modulation frequencies, $\boldsymbol{\omega}$, used to acquire the data. The cosine and sine transforms of the decay at the measurement frequencies are the elements of $\mathbf{p}$ and $\mathbf{q}$, respectively. Figure 8(b) and 8(c) illustrates two representations of the frequency-dependent decay of perylene emission. The first is a plot of the phase and modulation versus the modulation frequency. The second is a plot of the Fourier coefficients, $\mathbf{q}$ and $\mathbf{p}$, versus modulation frequency.

2.2.4 Multiexponential Decays

Before leaving this brief introduction to dynamic measurements, a few words about multiple fluorophores and fluorophores in nonideal solutions are in order here. When a fluorophore is solvated by a nonideal solution, the number of processes affecting the deactivation of the

Figure 8 Frequency-domain measurement of perylene emission. (a) Oscillating excitation and demodulated, phase (Φ) retarded perylene emission. (b) Phase and modulation of perylene emission as a function of excitation modulation frequency. (c) Fourier coefficients of decay as a function of excitation modulation frequency.

excited state increases. If the fluorophore is solubilized in a microheterogeneous environment, e.g. in a biomembrane or surfactant aggregate, the fluorophore may decay at a range of rates if the variations in the fluorophore environments lead to differences in relaxation rates. In this case, a distribution of lifetimes will describe the emission decay as shown in Equation (13)

$$\underline{I_{\mathrm{f}}(\mathbf{t})} = \sum_{\tau}^{\mathrm{T}} \alpha(\tau)\mathrm{e}^{-\mathbf{t}/\tau} \tag{13}$$

where the pre-exponential factor, $\alpha(\tau)$, constitutes the lifetime distribution. Figure 9 illustrates the lifetime distribution and time-dependence of the emission of dilute concentrations of pyrene in microheterogeneous media such as lipids or surfactants after pulsed excitation.[27] The monoexponential decay that has the same average decay constant is shown for comparison.

It is often the case that first-order kinetics describe the decay and interactions of the fluorescent components of a sample. If a sample contains n components, Equation (4) becomes Equation (14)

$$\frac{\mathrm{d}}{\mathrm{dt}}\begin{vmatrix} z_1 \\ \vdots \\ z_n \end{vmatrix} = \begin{vmatrix} k_{11} & \cdots & k_{1n} \\ \vdots & \ddots & \vdots \\ k_{n1} & \cdots & k_{nn} \end{vmatrix} \begin{vmatrix} z_1 \\ \vdots \\ z_n \end{vmatrix} + \mathrm{e}\begin{vmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{vmatrix} = \mathbf{Kz} + \mathrm{e}\mathbf{I} \tag{14}$$

The elements of $\mathbf{z}$ are the instantaneous concentrations of the excited fluorophores. The diagonal elements of $\mathbf{K}$ (the transfer matrix) are the decay constants of the sample components, the off-diagonals are the rates of conversion between the excited sample components. The vector function $\mathrm{e}\mathbf{I}$ is the driving or input function that produces the excited-state populations, i.e. the laser pulse in time-resolved measurements.

For time-domain experiments, assuming excitation powers well below saturating intensities, the solution of this system of equations is a time-dependent vector of excited state concentrations. Equation (15) shows

$$\mathbf{z}(t) = \mathbf{W}\mathrm{e}^{\mathbf{\Lambda}\mathrm{t}}\mathbf{W}^{-1}\mathbf{z}_0 \tag{15}$$

where $\mathbf{W}$ is a matrix whose columns are the eigenvectors of the matrix $\mathbf{K}$ (i.e. $\mathbf{KW} = \mathbf{W\Lambda}$), $\mathrm{e}^{\mathbf{\Lambda}t}$ is a matrix that has the exponential of the product of the observation time and decay constants (eigenvalues of $\mathbf{K}$) on the diagonal, and $\mathbf{z}_0$ is a vector of the initial concentrations of the emitting excited states. Each component of this solution is a combination of the exponentials that decay at rates given by elements of $\mathbf{\Lambda}$. Figure 10 is a simulation of the time-dependence of pyrene monomer and excimer emission after pulsed excitation.[28]

Writing this solution at all observation times in matrix format yields Equation (16):

$$\mathbf{Z}^{\mathrm{T}} = \mathbf{W\Gamma L}^{\mathrm{T}} \tag{16}$$

where the columns of $\mathbf{Z}$ and $\mathbf{L}$ are the decay profiles of the sample components and their constituent exponentials, respectively. The diagonal elements of $\mathbf{\Gamma}$ are concentration factors. When the fluorophores do not interact in the excited state, the $\mathbf{K}$ is diagonal and $\mathbf{W}$ is an identity matrix. Each component decays monoexponentially with a decay rate equal to the inverse excited state lifetime. When there is an excited state reaction, $\mathbf{K}$ is not diagonal nor is $\mathbf{W}$ an identity matrix. Each is a combination of n

Figure 10 Simulated time-resolved emission decay of pyrene monomer (- - - - -) and diffusion-controlled excimer (———) in isotropic solution. (Rates based on Birks et al.[28])

exponentials that have decay constants that are the eigenvalues of **K** rather than the inverses of the component excited state lifetimes.

2.3 Anisotropy Measurements

2.3.1 Steady-state Anisotropy Measurements

The steady-state fluorescence intensity also depends on the polarization of the excitation. When randomly distributed molecules frozen in rigid solution are excited by a pulse of linearly polarized light, molecules that have their absorption dipole aligned with the electric vector of the excitation have the largest probability of absorbing the light (photoselection). If these molecules fluoresce, the emitted light also is polarized because the positions of the molecules are fixed in the frozen solution. If the solution is not frozen, the emission polarization (or its corollary, the anisotropy) decays with time as Brownian rotations and other molecular motions randomize the orientation of the excited molecules in the solution. The fluorescence anisotropy decay is a function of many sample properties including the fluorophore shape and size, the solvent viscosity and temperature and fluorophore dynamics such as rotations, torsional motion and conformational changes. Consequently, time-dependent anisotropy measurements are a source of information regarding molecular structure and photophysical processes that affect molecular structure.

The emission polarization can be measured using the anisotropy, r, or the polarization, P. These parameters are defined in Equations (17) and (18):

$$\mathrm{r} = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} = \frac{I_{\parallel} - I_{\perp}}{I_{\mathrm{f}}} \tag{17}$$

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \tag{18}$$

where $I_{\parallel}$ and $I_{\perp}$ are the intensities of fluorescence observed through parallel and perpendicular polarizers, respectively. The two measurements are completely analogous but it is more convenient to use the anisotropy in the analysis of multicomponent systems because r is a simple weighted average of the component anisotropies, as shown in Equation (19)

$$\mathrm{r} = \sum_{k}^{K} \alpha_k \mathrm{r}_k \tag{19}$$

where α_k is the fraction of the steady-state intensity emitted by the kth sample component.

When the fluorophore position is immobilized, the anisotropy is a measure of the average angular displacement of the emission dipole from the absorption dipole.[29] When the fluorophore is in motion, the polarization of the emission depends on the rate at which the molecules rotate away from their initial configuration. The steady-state anisotropy is the time-average of the time-dependent anisotropy (see the next section). In the case of spherical molecules, the steady-state anisotropy is given by Equation (20)

$$\mathrm{r} = \frac{\mathrm{r}_0}{1 + \tau_{\mathrm{f}}/\tau_{\mathrm{c}}} = \frac{\mathrm{r}_0}{1 + 6D\tau_{\mathrm{f}}} \tag{20}$$

In this expression, r_0 is the limiting or fundamental anisotropy (the anisotropy observed in the absence of any depolarization), τ_{f} is the fluorescence lifetime (the average lifetime of the excited state after photoexcitation), τ_{c} is the rotational correlation time (the inverse of the fluorophore rotational rate multiplied by six). D is called the fluorophore rotational diffusion coefficient. The rotational diffusion coefficient can be related to the solvent viscosity and molecular volume by the Stokes–Einstein equation, as shown in Equation (21):

$$6D = \frac{RT}{\eta V} \tag{21}$$

where R is the gas constant, T is the temperature, η is the macroscopic solvent viscosity and V is the molar volume of the fluorophore.

2.3.2 Time-resolved Anisotropy Measurements

Time-resolved anisotropy measurements depend on the fluorophore volume, solvent viscosity and temperature just as steady-state measurements do. Investigators have used dynamic anisotropy measurements in a variety of studies. Some examples include measuring solute rotation in biomembranes[30] and polymers, monitoring protein folding,[31] studies of ligand binding to macromolecules[32] and solute interaction with chromatographic surfaces.[33]

In the case of spherical molecules, the anisotropy decay is monoexponential as shown in Equation (22)

$$\mathbf{r(t)} = \mathrm{r}_0 \mathrm{e}^{-\mathbf{t}/\tau_{\mathrm{c}}} \tag{22}$$

The decay constant is the inverse rotational correlation time which is the inverse of six times the rotational diffusion coefficient (see Equations 20 and 21). Since the depolarization depends on the shape of the molecule, substantial efforts were made to extend the theoretical descriptions to include nonspherical molecules so that shape and orientational information could be recovered from polarization measurements. The most complete theoretical treatments accomplish this by solving a generalized rotational diffusion equation and calculating the intensity of fluorescence emission in the directions parallel and perpendicular to the excitation electric vector.[34] These treatments predict that the fluorescence anisotropy decay of an asymmetric molecule is comprised of five exponential components. The generalized

Figure 11 Time-resolved anisotropy decay of perylene in methanol. (Reproduced by permission of the American Institute of Physics from Barkley et al.[36])

time-dependent anisotropy is given by Equation (23)

$$\begin{aligned}\mathbf{r(t)} = 0.3[&4\varsigma_{12}e^{-3(D_3+D)\mathbf{t}} + 4\varsigma_{23}e^{-3(D_1+D)\mathbf{t}} \\ &+ 4\varsigma_{31}e^{-3(D_2+D)\mathbf{t}} + (\Phi+\Psi)e^{-(6D+2\Delta)\mathbf{t}} \\ &+ (\Phi-\Psi)e^{-(6D-2\Delta)\mathbf{t}}]\end{aligned} \tag{23}$$

where D_i, D and Δ are functions of the rotation tensors (rotational coefficients around the molecular axes), ς_{ij}, Φ and Ψ are functions of the fluorophore absorption and emission transition moments. Here, the difficult task of analyzing complex exponentials is compounded by the fact that two pairs of the five decay constants are typically close and the fact that individual fluorophores within a single macromolecule can decay and/or rotate independently.[35] Figure 11 illustrates the time-dependence of perylene anisotropy.[36] Perylene is a symmetric disk-shaped molecule such that $D_1 = D_\parallel$ and $D_2 = D_3 = D_\perp$. Equation (23) reduces to a triple exponential decay.

2.4 Quenching Measurements

2.4.1 Steady-state Quenching Measurements

Quenchers are solutes that attenuate fluorophore emission. Quenching measurements reveal the accessibility of fluorophores to the quencher and thus information about the structure of the medium around the fluorophore.[8] This approach can used to determine if a chromophore is buried deeply within a macrocycle or extended near the surface.[37] Quenching measurements can also be used to measure how well a surfactant or other delivery system sequesters molecules from the bulk solvent.[38]

Quenching mechanisms fall into two primary classes. Static quenchers prevent fluorophores from being excited; dynamic quenchers increase the rate of excited state deactivation through collisional processes. Combinations of both mechanisms can be observed simultaneously in complex media. The dependence of the steady-state fluorescence intensity on quencher concentration in either case is given by Equation (24)

$$\frac{I_f(0)}{I_f([Q])} = 1 - K_Q[Q] \tag{24}$$

$I_f(0)$ is the intensity of fluorescence at zero quencher concentration, K_Q is the quencher constant. In static quenching, K_Q is the equilibrium constant for the complexation reaction between the fluorophore and quencher. In dynamic quenching, K_Q is the product of the fluorophore lifetime and the biomolecular quenching constant. Static and collisional quenching can be distinguished by dynamic measurements, which will be discussed in the next section.

2.4.2 Time-resolved Quenching Measurements

Lifetime measurements distinguish static and dynamic quenching. In the case of static quenching, the duration of the excited state is unchanged. Only the number of fluorophores being excited is reduced, so the ratio of unquenched to quenched lifetimes is always one. Dynamic quenchers reduce the excited state lifetime and, proportionately, the steady-state intensity. Therefore, the quenching constant indicated by the

Figure 12 Stern–Volmer plots of dansylated creatine kinase quenching by acrylamide. F_0/F is the ratio of fluorescence intensity in the absence (F_0) and presence (F) of quencher. (Reproduced by permission of the Biophysical Society from Grossman.[39])

ratio of unquenched to quenched lifetimes and the ratio of unquenched to quenched intensities is the same for dynamic quenching. Specifically, Equation (25) shows

$$\frac{I_f(0)}{I_f([Q])} = 1 + k_q\tau_0[Q] = \frac{\tau_0}{\tau} \tag{25}$$

where $I_f(0)$ and τ_0 are the intensity of fluorescence and fluorophore lifetime at zero quencher concentration, respectively. Figure 12 illustrates the difference in the intensity and lifetime ratios. Figure 12 shows the Stern–Volmer plots of the quenching of labelled creatine kinase by acrylamide.[39] The lifetime ratios fall on straight lines, indicating collisional quenching. The intensity ratio exhibits the negative curvature, indicating that some of the fluorescent labels are partially sequestered from the acrylamide in the solution.

2.5 Energy Transfer Measurements

2.5.1 Steady-state Energy Transfer Measurements

Excited state energy can be transferred from one molecule (the donor) to another (the acceptor) without photon emission by the donor. This phenomenon occurs through dipole–dipole interactions when the donor emission spectrum overlaps the acceptor excitation spectrum and the molecules are spatially close ($\sim\leq$50 Å). Specifically, the rate of Forster energy transfer[40] is given by Equation (26)

$$k_{ET} = (8.71 \times 10^{23})\frac{\kappa^2\phi_D J}{d^6 n^4}k_D \tag{26}$$

The variables ϕ_D and k_D represent the fluorescence quantum yield and decay time (inverse lifetime) of the donor, respectively. The variables d and κ^2 represent the distance between and relative orientation of the donor–acceptor pair, respectively. The overlap integral J measures the overlap between the donor emission spectrum and acceptor excitation spectrum. The solvent refractive index is n.

The energy transfer efficiency, E, which is directly related to the donor–acceptor distance, can be measured from steady-state intensities as shown in Equation (27)

$$E = \frac{D_F^6}{D_F^6 + d^6} = 1 - \frac{I_D([A])}{I_D(0)} \tag{27}$$

The Forster distance D_F is the distance at which the energy transfer rate is equal to the donor decay rate so that 50% of donor molecules relax via energy transfer. $I_D(0)$ is the fluorescence emission intensity from the donor in the absence of acceptor, $I_D([A])$ represents donor intensities in the presence of acceptor. The decrease in the donor fluorescence and concomitant increase in acceptor fluorescence as the acceptor concentration is increased is shown in Figure 13.

Figure 13 Energy transfer between tryptophan in human serum albumin (HSA) (excited at 295 nm) and bound 3-hydroxyflavone. (a) 40 μM HSA; (b) 40 μM HSA/20 μM 3HF; (c) 40 μM HSA/40 μM 3HF; (d) 40 μM HSA/60 μM 3HF; (e) 40 μM HSA/40 μM 3HF. All in pH 7 HEPES.

2.5.2 Dynamic Energy Transfer Measurements

When an energy transfer donor decays in the presence of an acceptor, the decay of the donor is given by Equation (28)

$$\underline{I_D}([A], \mathbf{t}) \propto \sum_d^{D_{max}} \alpha_d e^{-\mathbf{t}/\tau_0 + k_{ET}\mathbf{t}} = \sum_d^{D_{max}} \alpha_d e^{-\mathbf{t}/\tau_0[1+(D_F/d)^6]} \tag{28}$$

where D_{max} is the maximum donor–acceptor distance (see section 2.5.1 for other definitions). If the transfer occurs in viscous solvent (so that the donor-to-acceptor distance is fixed during the excited state lifetime) and the concentration is low (to prevent intermolecular interactions), the vector α_d represents the distribution distances between the donor and acceptor. The width of the distribution reflects the range of donor-to-acceptor distances in the system. If donor and acceptor are bound to fixed sites, e.g. on a protein, then $\boldsymbol{\alpha}_d$ represents a series of discrete values.

The energy transfer rate (Equation 26) has been called the spectroscopic ruler.[41] Determination of the distance distribution from the donor decay yields mean distances and conformational information regarding the system being monitored. The steady-state and dynamic energy transfer measurements are used to measure the distance between sites in macromolecular systems.[42] They are an important source of information regarding

the structure of systems that have not been crystallized or are not amenable to multidimensional nuclear magnetic resonance (NMR) studies.

2.6 Multidimensional Measurements

2.6.1 Steady-state Multidimensional Measurements

A multidimensional data set is produced when the fluorescence emitted by a sample is monitored as a function of the simultaneous variation of two or more measurement variables. The combination of independent measurement variables produces a selectivity increase that is inversely proportional to the correlation in the constituent responses to the individual variables. In many cases, the selectivity increase is sufficient to enable the analyst to resolve the sample constituents, or monitor an analyte in the presence of contaminants.

The most well-known type of steady-state multichannel fluorescence measurement is the intensity measured as a function of the excitation and emission wavelengths. The resulting map has been called the excitation–emission matrix (EEM)[11] and the total fluorescence spectrum.[43] The EEM of a single component sample is the outer product of the excitation and emission spectra of the fluorophore, as shown in Equation (29)

$$\mathbf{M}(\boldsymbol{\lambda}_{ex}, \boldsymbol{\lambda}_{em}) = \gamma \mathbf{x}(\boldsymbol{\lambda}_{ex})\mathbf{y}(\boldsymbol{\lambda}_{em})^{T} \tag{29}$$

where **M** represents the EEM, **x** the fluorophore excitation spectrum and **y** the fluorophore emission spectrum. The scalar γ is a concentration dependent proportionality constant.

The EEM of a dilute multicomponent sample is the sum of the K EEMs, $\mathbf{M}_k$, of the individual fluorophores that comprise the sample. Equation (30) shows

$$\mathbf{M} = \sum_{k}^{K} \mathbf{M}_k = \sum_{k}^{K} \gamma_k \mathbf{x}_{\cdot k} \mathbf{y}_{\cdot k}^{T} = \mathbf{X}\boldsymbol{\Gamma}\mathbf{Y}^{T} \tag{30}$$

The excitation and emission spectra of the sample components are stored in the columns of matrices **X** and **Y**, respectively. An isometric plot of a mixture of anthracene and perylene is shown in Figure 14.

2.6.2 Time-resolved Multidimensional Intensity Measurements

Multichannel acquisition of dynamic data also produces selectivity increases. All of the experimental variables discussed here, λ_{ex}, λ_{em}, φ_{ex}, [Q], and [A] can be combined with time, or equivalently excitation modulation frequency, to produce multidimensional data sets.

Figure 14 EEM of perylene and anthracene mixture in ethanol.

For example, the emission-time resolved decay matrix, **D**, is the sum of the outer products of the component emission spectra, $\mathbf{y}_l$, and intensity decay profiles, $\mathbf{z}_l$, as shown in Equation (31)

$$\mathbf{D} = \sum_{l}^{L} \mathbf{y}_l \mathbf{z}_l'^{T} = \mathbf{Y}\mathbf{Z}^{T} \tag{31}$$

In dilute solutions of fluorophores that do not interact (**K** in Equation 14 is diagonal), the decay profiles are pure exponentials, $\mathbf{l}_i$, scaled by a concentration factor, γ_u. The decay constants of these exponentials are the fluorophore decay rates. Equation (32) shows

$$\mathbf{D} = \mathbf{Y}\boldsymbol{\Gamma}\mathbf{L}^{T} \tag{32}$$

where the concentration factors, i.e. diagonal elements of $\boldsymbol{\Gamma}$, are the initial excited state concentrations of the sample components. When the sample fluorophores participate in excited state reactions (see section 2.2.4), the decay of each fluorophore is affected by the decay of the other components. In this case, the decay is a combination of exponentials, reflecting the structure of the photokinetic transfer matrix describing the excited state reaction. Equation (33) shows

$$\mathbf{D} = \mathbf{Y}\mathbf{W}\boldsymbol{\Gamma}\mathbf{L}^{T} \tag{33}$$

The columns of the matrix **W** are the eigenvectors of the photokinetic matrix, **K**; the diagonal elements of $\boldsymbol{\Gamma}$ are concentration factors given by $\mathbf{W}^{-1}\mathbf{z}_0$ where $\mathbf{z}_0$ are initial intensities of the emission decays. The decay constants of the exponentials are the eigenvalues of **K**. The time-resolved emission-decay matrix of a mimetic photosynthetic porphyrin[44] is shown in Figure 15.

Multidimensional data acquisition facilitates analysis of multicomponent samples without separation. This is especially useful in kinetic studies[45] because analyses can be performed in the presence of influential sample components. Calibration methods for multidimensional

data sets can provide robust quantitation in spite of the presence of sample contaminants.[12]

3 INSTRUMENTATION FOR ULTRAVIOLET/VISIBLE MOLECULAR FLUORESCENCE MEASUREMENTS

3.1 Absorbance Spectrophotometer

Absorbance spectrophotometers are available in several configurations. All of them include a light source, wavelength selection device, sample holder and photon detector. Figure 16 is a schematic of a typical apparatus for measuring steady-state absorbance data and monitoring millisecond kinetics at multiple wavelengths. A deuterium lamp provides broadband excitation from 200 to 800 nm. The light transmitted by the sample is collected by optics, dispersed by a spectrograph and focused onto the surface of a photodiode array. Instrument noise in most absorbance spectrophotometers is a combination of detector dark current (zero percent transmittance (0% T) noise), source flicker (frequency dependent (1/f) noise) and signal shot noise. Error from these sources is normally distributed.

3.2 Time-resolved Spectrofluorometer

Spectrofluorometers are constructed using many of the same components used to construct absorbance spectrophotometers, but the detector–sample axis is 90° to the source–sample axis to minimize collection of scattered light. The classical time-resolved method is time correlated single photon counting. A high repetition rate laser can acquire an entire decay profile in a few seconds. Figure 17 is a schematic of an instrument

Figure 17 Diagram of general-purpose time-resolved spectrofluorimeter, Photon Technologies International, Inc. TimeMaster. (Reproduced by permission of Photon Technology, Int., Inc.)

equipped to measure steady-state and time-resolved fluorescence. The source depicted is a flash lamp, but pulsed lasers are commonly used in this application. The decay is detected by a gated photomultiplier tube. The monochromator in the detection channel permits the measurement of steady-state emission spectra and wavelength dependent decays. The spectrometer has two emission channels equipped with polarizers (T-format) to enable simultaneous measurement of parallel and perpendicular polarized emission. In this type of instrument, measurement errors are produced by detector dark current and analyte shot noise and source flicker. These noise sources are normally distributed. This contrasts the Poisson distributed errors of time-correlated single photon counting measurements.

3.3 Frequency-domain Spectrofluorometer

Figure 18 is a partial schematic of a versatile instrument for measuring steady-state and frequency-domain fluorescence. The source, a xenon arc lamp, is modulated at rates up to 250 MHz by a Pockels cell. The reference excitation beam and sample emission are detected by photomultiplier tubes. These signals are acquired by modulating the gain of both detectors at a frequency close, but not equal to, the source modulation frequency. When this cross-correlation frequency mixes with the signal, the signal carrier frequency is reduced to the difference in the source and detector frequencies. The monochromator in the detection channel permits the measurement of steady-state emission spectra and wavelength dependent decays. The spectrometer has two emission channels equipped with polarizers (T-format) to enable simultaneous measurement of parallel and perpendicular polarized emission. This instrument measures the modulation ratio and phase lag of the emission relative to those of the excitation. Source flicker, radiofrequency pick-up (from synthesizer harmonic noise), synthesizer phase noise and detector dark current are the significant sources of error in this instrument.[46] These sources are normally distributed.

4 DATA ANALYSIS OF ULTRAVIOLET/VISIBLE MOLECULAR ABSORBANCE AND FLUORESCENCE MEASUREMENTS

4.1 Classification of Data Analysis Methods

There are many similarities in the data types and mathematical expressions outlined in section 2. Consequently, three classes of procedure provide most analysis for absorbance and fluorescence data. To recover sample information from steady-state data, we need programs that model the relationship between the spectral property

(I_f, r, etc.) and the sample property of interest ([c], V, etc.). The model then can be used to predict the properties of unknown samples. This is the function of regression methods, which are discussed in section 4.2. In dynamic measurements, the sample properties of interest are related to the decay constants or pre-exponential factors. Therefore, decay analysis methods, discussed in section 4.3, are needed to analyze dynamic data. The multivariate data sets, steady-state and dynamic, can be factored into the responses of the sample components. In some cases, the resolved responses will require additional analysis, e.g. decay analysis. Matrix factorization methods are discussed in section 4.4. Prototypical procedures from each of these classes and the primary concerns of the analyst applying them to absorbance and fluorescence data will be discussed in the following sections.

4.2 Regression Methods

4.2.1 Linear Least Squares Regression

When the ideal (noise-free) instrument response of a sample is a known (or suspected) to be a linear function of a single experimental (independent) variable, the parameter values that define the response model can be determined by linear least squares regression (LLSR). The measured response, **g**, to changes in the experimental variable, **f**, is the combination of a simulated response, **s**, and measurement error **ξ**. A single coefficient, β, defines the contributions of the variable to the simulated response. In general terms, this relationship is given by Equation (34)

$$\mathbf{g} = \mathbf{s}(\beta, \mathbf{f}) + \boldsymbol{\xi} \tag{34}$$

where **g**, **s** and **ξ** are N element vectors. The values of the independent variable are the N elements of the vector, **f**, and β is a scalar. For the sake of a more concrete discussion, let us consider Equation (34) a model of a static quenching study (cf. Equation 24). The quencher concentration is the independent variable, **f**. The ratio of fluorescence intensities in the absence and presence of quencher is the response, **g**. The quenching constant is β.

There are several equivalent formalisms for describing the principles of least-squares methods. The discussions that follow are close to those given by Scales.[47] The simulation, **s**, fits the instrument response, **g**, in the least-squares sense when the parameters, β, minimize the residuals. The residuals are measured by the sum of the squared differences between the response and the simulation, i.e. $\rho = \sum_n^N \xi_n^2$. This sum is minimized when its first derivative with respect to β is zero, as shown in Equation (35)

$$\frac{\partial \rho}{\partial \beta} = \frac{\partial}{\partial \beta}[\mathbf{g} - \mathbf{s}(\mathbf{f}, \beta)]^{\mathrm{T}}[\mathbf{g} - \mathbf{s}(\mathbf{f}, \beta)] = 0 \tag{35}$$

Least squares parameters that meet this criterion have the highest probability of being the correct value, i.e. producing a simulation that fits the instrument response. The distribution of simulated responses around the experimental response reveals the inverse relationship between the experimental error and coefficient probability. Notice that $p(\beta)$ increases as the residuals decrease, as shown in Equation (36)

$$p(\beta) \propto \exp\left\{ \frac{1}{2} \sum_n^N \left(\frac{g_n - s_n(\mathbf{f}, \beta)}{\sigma_n} \right)^2 \right\} \tag{36}$$

The variable σ_n denotes the standard error in the nth (of N) measurement of **g**, i.e. the intensity ratio in our quenching example. Equation (36) reveals why it is so important to ensure that residuals are drawn from a normal distribution when applying least-squares methods. If the residuals are not normally distributed, least-squares parameters will not have the highest probability of representing the data accurately.

The parameter, e.g. quenching constant, which minimizes the residuals, is determined using Equations (37–39):

$$\rho(\beta) = \sum_n^N \xi_n^2 = \boldsymbol{\xi}'\boldsymbol{\xi} = (\mathbf{g} - \mathbf{f}\beta)^{\mathrm{T}}(\mathbf{g} - \mathbf{f}\beta)$$
$$= \mathbf{g}^{\mathrm{T}}\mathbf{g} - 2\beta\mathbf{f}^{\mathrm{T}}\mathbf{g} - \beta^2\mathbf{f}^{\mathrm{T}}\mathbf{f} \tag{37}$$

$$\frac{\partial \rho}{\partial \beta} = -2(\mathbf{f}^{\mathrm{T}}\mathbf{g} + \mathbf{f}^{\mathrm{T}}\mathbf{f}\beta) = 0 \tag{38}$$

$$\hat{\beta} = (\mathbf{f}^{\mathrm{T}}\mathbf{f})^{-1}\mathbf{f}^{\mathrm{T}}\mathbf{g} \tag{39}$$

The circumflex (ˆ) indicates that $\hat{\beta}$ is an estimate. Remember that $\mathbf{f}^{\mathrm{T}}\mathbf{f}$ and $\mathbf{f}^{\mathrm{T}}\mathbf{g}$ are scalar values. They are more familiar than they look. If **g** and **f** were written as mean-centered vectors, i.e. replaced by $\mathbf{g} - \bar{\mathbf{g}}$ and $\mathbf{f} - \bar{\mathbf{f}}$, respectively, and expanded as sums rather than dot products, Equation (39) would be identical to Equation (40), the formula taught to undergraduates for calculating the slope of a line.[48]

$$\hat{\beta} = \frac{N\sum_n^N f_n g_n - \sum_n^N f_n \sum_i^N g_n}{N\sum_n^N f_n^2 - \left(\sum_n^N f_n\right)^2} \tag{40}$$

4.2.2 Multiple Linear Regression

Multiple linear regression (MLR)[20] is the extension of LLSR to the analysis of the responses of several samples to several independent variables. The regression determines the values of parameters that model the dependence of the response on experimental values. The

procedure is based on the idea that the observed sample response is a linear combination of the sample property of interest. For example, the steady-state fluorescence intensity of a K component mixture usually can be modeled as a linear combination of the intensities and concentrations of the K components (Beer's law). At least K simultaneous equations are required to determine the concentrations. If the sample fluorescence is measured at K or more emission or excitation wavelengths, the concentrations of the components can be recovered. In the following section, measured response, **G**, the experimental variable, **F**, the coefficients, **B**, and measurement error Ξ are the matrix counterparts of these quantities in section 4.2.1. Think of **G**, **S** and Ξ as being constructed by arranging the N element responses for M samples into a table (matrix). **F** must be an $N \times K$ matrix and **B** must be a $K \times M$ matrix in order to estimate **G**.

MLR consists of two steps: calibration and quantitation. Calibration consists of measuring the response of standards or samples that can be assayed reliably using alternative methods. In matrix format the calibration model is given by Equation (41)

$$\mathbf{G}_{\text{std}} = \mathbf{F}\mathbf{B}_{\text{std}} + \boldsymbol{\Xi} \tag{41}$$

In the steady-state fluorescence example, **G** is the matrix of fluorescence intensities at **K** or more wavelengths, **B** is the matrix of concentrations and **F** a matrix of spectral profiles.

In the calibration step, the predictor matrix, $\mathbf{F}^{-}_{\text{MLR}}$, is calculated from $\mathbf{G}_{\text{std}}$ and $\mathbf{B}_{\text{std}}$, as shown in Equation (42)

$$\mathbf{F}^{-}_{\text{MLR}} = \mathbf{B}_{\text{std}}\mathbf{G}^{\text{T}}_{\text{std}}(\mathbf{G}_{\text{std}}\mathbf{G}^{\text{T}}_{\text{std}})^{-1} \tag{42}$$

The predictor matrix is written as a special inverse (superscript minus) to emphasize the fact that solving for **B** in Equation (41) is the inverse of regression problems traditionally discussed in statistics tutorials. The values of $\mathbf{F}^{-}_{\text{MLR}}$ calculated by Equation (42) minimize the sum of squares of the elements of Ξ.

In the quantitation step, the properties of a sample response, e.g. component concentrations, are determined using $\mathbf{F}^{-}_{\text{MLR}}$. Equation (43) shows

$$\widehat{\mathbf{B}}_{\text{sample}} = \mathbf{F}^{-}_{\text{MLR}}\mathbf{G}_{\text{sample}} \tag{43}$$

The validity of the model embodied in $\mathbf{F}^{-}_{\text{MLR}}$ is measured by the sum of squares of the prediction error, σ^2_{PRESS}. The prediction error depends on how well $\mathbf{F}^{-}_{\text{MLR}}$ reproduces the values of the calibration set, as shown in Equations (44) and (45)

$$\widehat{\mathbf{B}}_{\text{std}} = \mathbf{F}^{-}_{\text{MLR}}\mathbf{G}_{\text{std}} \tag{44}$$

$$\sigma_{\text{PRESS}} = \sum_{m}^{M}\sum_{k}^{K}[(\mathbf{B}_{\text{std}})_{\text{km}} - (\widehat{\mathbf{B}}_{\text{std}})_{\text{km}}]^2 \tag{45}$$

MLR calibrations perform well under ideal conditions. For multivariate spectral measurements a calibration (standard) set is ideal when it is free of interfering contaminants, matrix effects, interactions between standards, severely overlapped standard spectra and has a good signal-to-noise ratio. The method can be used for simultaneous determination of sample components, but it is usually applied with other regression methods[49] because it is less effective when the component spectra are strongly overlapped.

4.2.3 Principle Components Regression and Partial Least Squares Projection

MLR is called a 'hard' modeling technique because it establishes a correlation between experimental responses and sample properties, i.e. physically observable quantities. MLR incorporates all the information in the calibration set, including measurement error and contaminants, into the calibration matrix. Soft modeling methods such as principal components regression (PCR) and partial least squares (PLS)[20] minimize these limitations of MLR by transferring information to the prediction matrix, $\mathbf{F}^{-}$, more selectively.

All data matrices can be expressed as combinations of orthonormal basis vectors or factors, as shown in Equation (46)

$$\mathbf{G} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^{\text{T}} = \mathbf{Q}\mathbf{V}^{\text{T}} \tag{46}$$

The columns of **V** summarize the variance, i.e. collect the shapes, distributed along the rows of **G**. The first column of **G** summarizes all the variance of **G**, so it is similar to the average of the rows of **G**. The second column of **V** summarizes all the variance not captured by the first column of **V**. Consequently, it is orthogonal (completely uncorrelated) to the first. This successive extraction of uncorrelated vectors continues until all the variance of **G** is captured. The rows of **Q** are called scores because they reflect how important each column of **V** is to each row of **G**. The number of columns of **V** required to describe the rows of **G** is the rank of **G**. Ideally, the rank of a spectral matrix is K, the number of components absorbing or emitting photons. Experimentally, the rank of a matrix will equal the smaller matrix dimension because of measurement error. In this case, the number of components is the pseudorank of the matrix. The first K columns of **V** (primary principal components) describe the spectral response while the rest (secondary principal components) describe the measurement error. Eliminating the contribution of factors associated with measurement error in Equation (46) reduces the measurement error in the matrix.

In PCR, the response matrix, **G**, is factored into orthogonal basis vectors and scores and the secondary principal components are discarded. The product of the

remaining components is an estimate of **G** that contains significantly lower amounts of measurement error, as shown in Equation (47)

$$\widehat{\mathbf{G}}_{\text{std}} = \breve{\mathbf{Q}}\breve{\mathbf{V}}^{\text{T}} \tag{47}$$

where the superpositioned curve indicates that the secondary columns of **Q** and **V** were discarded prior to the calculation of $\widehat{\mathbf{G}}$. Procedures that estimate the pseudorank are discussed in section 5.2. When all vectors **V** are used to reconstruct $\mathbf{G}_{\text{std}}$, the PCR and MLR results are identical.

The PCR calibration is based on the same linear model used in MLR, but the predictor matrix is calculated from the scores of the response matrix. The calibration model is shown in Equation (48)

$$\mathbf{G}_{\text{std}} = \mathbf{Q}\mathbf{V}^{\text{T}} = \mathbf{F}\mathbf{B}_{\text{std}} + \boldsymbol{\Xi} \tag{48}$$

The predictor matrix is calculated from the primary factors of $\mathbf{G}_{\text{std}}$, as shown in Equations (49) and (50)

$$\mathbf{F}^{-}_{\text{PCR}} = \mathbf{B}_{\text{std}}\breve{\mathbf{V}}^{\text{T}}\breve{\mathbf{Q}}(\breve{\mathbf{Q}}\breve{\mathbf{Q}}^{\text{T}})^{-1} \tag{49}$$

$$\widehat{\mathbf{B}}_{\text{sample}} = \mathbf{F}^{-}_{\text{PCR}}\mathbf{G}_{\text{sample}} \tag{50}$$

If the calibration standards of the steady-state fluorescence intensity example were collected using very dilute solutions, for example, the PCR prediction error would be lower than the MLR error. The predictor matrix estimated by MLR is an unbiased estimator of $\mathbf{G}_{\text{std}}$ but its elements can have large variances, leading to imprecise predictions.[50] In PCR, the predictor is biased (the values of $\mathbf{F}^{-}_{\text{PCR}}$ do not minimize the sum of squares of Ξ), but has a smaller variance and lower prediction error.

PCR constructs the prediction matrix using orthonormal factors of **G** calculated to capture the maximum variance of $\mathbf{G}_{\text{std}}$. These factors are calculated without regard to the calibration variables in $\mathbf{B}_{\text{std}}$. PLS methods factor $\mathbf{G}_{\text{std}}$ into orthogonal factors that are maximally correlated to the calibration variables.[50] This approach minimizes the large errors associated with highly correlated calibration variables. Theoretically, the PLS factors are calculated to minimize the prediction error rather than the residuals of $\mathbf{G}_{\text{std}}$, as shown in Equation (51)

$$\begin{aligned}\widehat{\mathbf{G}}^{\text{T}}_{\text{std}} &= \breve{\mathbf{T}}\breve{\mathbf{C}}^{\text{T}} \\ \text{B}^{\text{T}}_{\text{std}} &= \breve{\mathbf{T}}\breve{\mathbf{P}}^{\text{T}}\end{aligned} \tag{51}$$

Keep this straightforward principle in mind because the PLS algorithm is more difficult to understand than the MLR or PCR algorithms. The connection between the form of the predictor matrix and the calibration results is not obvious.

The following algorithm is called the PLS kernel algorithm. It is especially efficient when the number of responses is large and much larger than the pseudorank (number of variables).[51] After rank estimation, the calculation of **T**, **C** and **P** consists of three steps that are repeated until the factors needed to reconstruct $\mathbf{G}_{\text{std}}$ and $\mathbf{B}_{\text{std}}$ have been determined. (Note: it was impossible to record the algorithm here without using variables that have other meanings elsewhere in the article. The variables **T**, **P**, **C**, **W** and **R** have no connection to their meanings elsewhere in the article.)

1. Calculate the basis vector, $\mathbf{t}_{\cdot 1}$, of $\mathbf{G}_{\text{std}}$ that is maximally correlated to $\mathbf{B}_{\text{std}}$. It is the most prominent eigenvector of $\mathbf{B}^{\text{T}}\mathbf{B}\mathbf{G}^{\text{T}}\mathbf{G}$ (subscripts dropped), given by Equation (52)

$$\mathbf{B}^{\text{T}}\mathbf{B}\mathbf{G}^{\text{T}}\mathbf{G}\mathbf{t}_{\cdot 1} = \mathbf{t}_{\cdot 1}\lambda_{11} \tag{52}$$

   where λ_{11} is the eigenvalue of $\mathbf{G}^{\text{T}}\mathbf{G}\mathbf{B}^{\text{T}}\mathbf{B}$, called the PLS kernel matrix.
2. Calculate $\mathbf{p}_{\cdot 1}$ and $\mathbf{c}_{\cdot 1}$, shown in Equations (53) and (54), which are the scores of the rows of $\mathbf{B}_{\text{std}}$ and $\mathbf{G}_{\text{std}}$ with respect to $\mathbf{t}_{\cdot 1}$.

$$\mathbf{p}_{\cdot 1} = (\mathbf{t}^{\text{T}}_{\cdot 1}\mathbf{B}^{\text{T}})(\mathbf{t}^{\text{T}}_{\cdot 1}\mathbf{t}_{\cdot 1})^{-1} \tag{53}$$

$$\mathbf{c}_{\cdot 1} = (\mathbf{t}^{\text{T}}_{\cdot 1}\mathbf{G}^{\text{T}})(\mathbf{t}^{\text{T}}_{\cdot 1}\mathbf{t}_{\cdot 1})^{-1} \tag{54}$$

   Calculate $\mathbf{w}_{\cdot 1}$, the weight of $\mathbf{t}_{\cdot 1}$ on the part of the rows of $\mathbf{G}_{\text{std}}$ that are correlated to the columns of $\mathbf{B}_{\text{std}}$. Equation (55) shows:

$$\mathbf{w}_{\cdot 1} = \mathbf{B}\mathbf{G}^{\text{T}}\mathbf{G}\mathbf{t}_{\cdot 1} \tag{55}$$

3. Subtract contributions of $\mathbf{t}_{\cdot 1}$ from $\mathbf{G}_{\text{std}}$ and $\mathbf{B}_{\text{std}}$ and return to step 1. Equation (56) shows

$$\begin{aligned}\mathbf{R}_{-1} &= \mathbf{I} - \mathbf{t}_{\cdot 1}\mathbf{t}^{\text{T}}_{\cdot 1} \\ \mathbf{G}^{\text{T}}_{-1}\mathbf{G}_{-1} &= \mathbf{R}_{-1}\mathbf{G}^{\text{T}}\mathbf{G}\mathbf{R}_{-1} \\ \mathbf{B}^{\text{T}}_{-1}\mathbf{B}_{-1} &= \mathbf{R}_{-1}\mathbf{B}^{\text{T}}\mathbf{B}\mathbf{R}_{-1}\end{aligned} \tag{56}$$

   $\mathbf{R}_{-1}$ is a projection matrix that removes contributions of $\mathbf{t}_{\cdot 1}$ from $\mathbf{G}^{\text{T}}\mathbf{G}$ and $\mathbf{B}^{\text{T}}\mathbf{B}$. Subtracting the contributions of $\mathbf{t}_{\cdot 1}$ insures that the subsequent columns of **T** will be orthogonal to $\mathbf{t}_{\cdot 1}$ and each other. The remaining columns (2 through K) of **T**, **P**, **C** and **W** are determined by repeating steps 1–3 until the number of factors indicated by rank estimation have been determined.

The predictor matrix is calculated from the scores of **B** and weights of **T** on **G** and **B**, as shown in Equation (57)

$$\mathbf{F}^{-}_{\text{PLS}} = \mathbf{W}(\mathbf{P}^{\text{T}}\mathbf{W})^{-1}\mathbf{C}^{\text{T}} \tag{57}$$

The correlation between **G** and **B** reduces the error of prediction in PLS regression compared to PCR and MLR. Equations (58) and (59) show

Figure 19 Regression vectors calculated by (a) MLR, (b) PCR, and (c) PLS from a calibration set consisting of four mixture emission spectra distorted by random noise and simulated baseline drifts. Spectra (d–e) estimated by regressors in (a–c) magnitude differences and PRESS values (inserts) show superiority of PLS in cases of collinear variables and instrument drift.

$$\widehat{\mathbf{B}}_{\text{std}} = \mathbf{F}_{\text{PLS}}^{-}\mathbf{G}_{\text{std}} \tag{58}$$

$$\sigma_{\text{PRESS}} = \sum_{m}^{M}\sum_{k}^{K} (\mathbf{B}_{\text{std}})_{\text{km}} - (\widehat{\mathbf{B}}_{\text{std}})_{\text{km}}{}^{2} \tag{59}$$

In the quantitation step, the properties of the sample responses are calculated using $\mathbf{F}_{\text{PLS}}^{-}$, as shown in Equation (60)

$$\mathbf{B}_{\text{sample}} = \mathbf{F}_{\text{PLS}}^{-}\mathbf{G}_{\text{sample}} \tag{60}$$

PLS improves quantitation when the calibration standards deviate from Beer's law because of matrix effects, instrument variations and contaminants. It is also more robust when the calibration standards are substantially correlated. All of these deviations are likely to be observed in the steady-state fluorescence intensity.

4.2.4 Application of Regression to Absorbance and Fluorescence Data

Regression methods can be used to recover any sample property that correlates the observed response to the experimental variable. For example, the correlation between the carcinogen metabolism and the habits (e.g. smoking) of workers exposed to polynuclear aromatic hydrocarbons has been modeled using MLR.[52] Most applications of regression methods in the literature involve simultaneous determination of multiple sample components using multiple wavelength absorbance and fluorescence intensity measurements. Figure 19 depicts the MLR, PCR and PLS regression vectors used to correlate a hypothetical set of mixture spectra to component concentrations. Regression methods have not been widely used by the biochemical/biophysical fluorescence community, though they could be used to calculate apparent viscosity from steady-state anisotropy of spherical probes, quenching constants and donor–acceptor distances. A list of selected applications of regression methods is provided in Table 1.[49,52–67]

4.3 Decay Analysis Methods

The development, application and interpretation of decay analysis methods is an active area of research and discussion. The field is dominated by nonlinear least squares and global target analysis. These methods are described in two of the following sections. The maximum

Table 1 Selected regression applications

entropy method (MEM) and multivariate frequency-domain decay analysis (MFDA) method are described because they are model-independent in that neither requires the analyst to select a model to describe the decay prior to the analysis.

4.3.1 Nonlinear Least-squares Fitting

Nonlinear least-squares fitting is a very widely used numerical approach to estimating the contribution of user-specified functions or models to experimental data. There are two types of least squares algorithms for determining parameter values when the model is not a linear function of the experimental variables. Gradient methods use the derivatives of the sum of the squared residuals (ρ) with respect to the parameters ($\boldsymbol{\beta}$) to identify the minimum in ρ. Function comparison (or direct search) methods minimize ρ by systematically searching the $\rho(\beta)$ response surface for the minimum value of ρ. These contrasting approaches are illustrated by the Levenberg–Marquardt[68] modification of the Gauss–Newton method (gradient) and the Nelder and Meade[69] simplex algorithm (function comparison). In general, gradient methods converge more quickly than function comparison methods. On the other hand, function comparison methods are easier to encode because they do not involve derivatives or matrix inverses. In the specific case of nonlinear least squares analysis, the derivatives of ρ are well known, therefore many programs are based on the faster convergence of gradient methods such as Levenberg–Marquardt.

In the Levenberg–Marquardt algorithm, the goal is to adjust the parameter values so that the residuals get smaller at each iteration, as shown in Equation (61)

$$\rho({}^{k+1}\boldsymbol{\beta}) = \rho({}^{k}\boldsymbol{\beta} + {}^{k}\mu{}^{k}\boldsymbol{\nu}) < \rho({}^{k}\boldsymbol{\beta}) \tag{61}$$

where $\rho({}^{k+1}\boldsymbol{\beta})$ is shorthand for $\rho[\mathbf{f}({}^{k+1}\boldsymbol{\beta})]$ and means the $(k+1)$st (next) iterate of ρ. As shown in Equation (62) each new parameter estimate, ${}^{k+1}\boldsymbol{\beta}$, is a combination of the previous iterate, ${}^{k}\boldsymbol{\beta}$, and a search vector, $\boldsymbol{\nu}$.

$${}^{k+1}\boldsymbol{\beta} = {}^{k}\boldsymbol{\beta} + \Delta\boldsymbol{\beta} = {}^{k}\boldsymbol{\beta} + {}^{k}\mu{}^{k}\boldsymbol{\nu} \tag{62}$$

where Δ denotes 'a change in parameter value'. The keys to the reduction in ρ are the length, ${}^{k}\mu$, and direction of the search vector, ${}^{k}\boldsymbol{\nu}$. In the neighborhood of a minimum any function can be expressed as a quadratic. This means that the minimum in ρ can be approximated by its Taylor expansion using the first two derivatives, as shown in Equation (63)

$$\rho({}^{k+1}\boldsymbol{\beta}) \cong \rho({}^{k}\boldsymbol{\beta}) + {}^{k}\mu(\underline{\nabla\rho})^{\mathrm{T}}{}^{k}\boldsymbol{\nu} + \tfrac{1}{2}{}^{k}\mu^{2k}\boldsymbol{\nu}^{\mathrm{T}}(\underline{\underline{\nabla^2\rho}})^{k}\boldsymbol{\nu} \tag{63}$$

where $\nabla\rho$ is the gradient (first derivative of ρ with respect to the parameters, $\boldsymbol{\beta}$) and $\underline{\underline{\nabla^2\rho}}$ is the Hessian, the matrix of second derivatives with respect to the parameters. As the minimization proceeds, the gradient, $\underline{\nabla\rho}$, approaches zero. (This is a central feature in Newton-type methods.) The updated gradient of ρ, ${}^{k+1}\underline{\nabla\rho}$, is given by Equation (64)

$${}^{k+1}\underline{\nabla\rho} \cong {}^{k}\underline{\nabla\rho} + {}^{k}\boldsymbol{\mu}{}^{k}\underline{\underline{\nabla^2\rho}}{}^{k}\boldsymbol{\nu} \tag{64}$$

Since the form of ρ is known explicitly, the gradient and Hessian can be written in terms of the residuals, $\boldsymbol{\xi}$, and parameters, $\boldsymbol{\beta}$. They are shown in Equations (65–67):

$$\rho = (\mathbf{f}-\mathbf{g})^{\mathrm{T}}(\mathbf{f}-\mathbf{g}) = \boldsymbol{\xi}^{\mathrm{T}}\boldsymbol{\xi}, \tag{65}$$

$$(\nabla\rho)_j = 2\sum_i^n \xi_i \frac{\partial\xi_i}{\partial\beta_j} = 2\mathbf{J}^{\mathrm{T}}\boldsymbol{\xi}, \tag{66}$$

$$(\nabla^2\rho)_{kj} = 2\sum_i^n \left\{ \frac{\partial\xi_i}{\partial\beta_k}\frac{\partial\xi_i}{\partial\beta_j} + \xi_i\frac{\partial^2\xi_i}{\partial\beta_k\partial\beta_j} \right\} = 2\mathbf{J}^{\mathrm{T}}\mathbf{J} + 2\boldsymbol{\xi}\circ\mathbf{H} \tag{67}$$

In these expressions, $\mathbf{J}$ and $\mathbf{H}$ are matrices describing the first and second partial derivatives of the residuals (elements of $\boldsymbol{\xi}$ not ρ) with respect to the parameter

vector elements. Substituting these expressions into Equation (64) and setting to zero yields Equation (68)

$$({}^{k}\mathbf{J}^{\mathrm{T}k}\mathbf{J} + {}^{k}\boldsymbol{\xi} \circ {}^{k}\mathbf{H})^{k}\boldsymbol{\nu} = -{}^{k}\mathbf{J}^{\mathrm{T}k}\boldsymbol{\xi} \tag{68}$$

The search direction $\boldsymbol{\nu}$ is determined by solving this system of equations. The Levenberg–Marquardt algorithm solves for $\boldsymbol{\nu}$ by ignoring the second derivatives of the residuals ($\boldsymbol{\xi}\cdot\mathbf{H}$) and adding a small diagonal increment $\mathbf{J}'\mathbf{J}$ to guard $\boldsymbol{\nu}$ from the consequences of strong correlations in the variables. The search direction is given by Equation (69)

$${}^{k}\boldsymbol{\nu} = ({}^{k}\mathbf{J}^{\mathrm{T}k}\mathbf{J} + {}^{k}\vartheta\mathbf{I})^{-1}(-{}^{k}\mathbf{J}^{\mathrm{T}}\boldsymbol{\xi}) \tag{69}$$

In practice, these equations are not solved by matrix inversion. Gaussian elimination is more reliable and robust. The increment ${}^{k}\vartheta$ must be large enough to insure that $\boldsymbol{\nu}$ leads to a reduction in ρ. Later in the optimization, ${}^{k}\vartheta$ must grow smaller at each iteration in order for the algorithm to converge on the optimal parameters. The size of this increment is determined by a linear search. The resulting descent direction is added to the previous parameter estimate, as shown in Equation (70)

$${}^{k+1}\boldsymbol{\beta} = {}^{k}\boldsymbol{\beta} + {}^{k}\boldsymbol{\nu} \tag{70}$$

The descent direction moves the estimate toward a zero-valued gradient. This process is repeated until $\mathbf{J}^{\mathrm{T}}\boldsymbol{\xi}$ meets some user-specified tolerance close to zero. The associated parameters simulate the experimental data with minimized residuals. If the parameters model decay data, the model is given by Equation (71)

$$\mathbf{g} = \beta_1 \mathrm{e}^{-\beta_2 \mathbf{t}} + \beta_3 \mathrm{e}^{-\beta_4 \mathbf{t}} + \cdots + \boldsymbol{\xi} \tag{71}$$

4.3.2 Global Target Analysis

Nonlinear least-squares algorithms are used in the analysis of a large number of data types, attesting to the power of the method. On the other hand, it is difficult to analyze complex decays accurately and unambiguously. Global target analysis has evolved from efforts to address this limitation.[4,70] The central feature of global analysis is the simultaneous analysis of several related experimental responses. The combined responses are analyzed as a group using a single model. The parameter values for each response are not only consistent with that particular response, but with all the responses in the set. In most cases, the confidence intervals around the parameter values are significantly reduced when compared to parameters recovered from the analysis of single responses. Consequently, parameters determined using global analysis have a higher probability of accuracy than their single response counterparts. Nonlinear least-squares fitting is the method of choice in most global analyses, but this method can be implemented using the optimization method of the analyst's choice. In fact, one of the earliest global analyses[71] used the method of moments[72] to determine the fluorescence lifetime from fluorescence decays.

The reduction in the parameter confidence intervals is a significant advance in itself. The enhanced sensitivity in the 'goodness of fit' observed in global analysis has a second important consequence. Physical model evaluation has become an integral part of many global analysis programs. Parameters can fit experimental responses well, yet have no physically meaningful interpretation. In order to avoid physically meaningless parameter values, global target analysis defines the simulated response in terms of physical invariants. Using this approach, a data set should be analyzed using several alternative models. The applicability of the models that were tested is quantified via error (i.e. residual) analysis. As long as the residuals are consistent with the spectrometer measurement error, the data can be associated with a model. It is important to remember that regardless of the goodness of fit, data analysis can only determine that a model is compatible with the data, not prove that a specific process is producing the emission. In general, parameters (pre-exponentials and decay constants) recovered from complex ($\geq$3 components) exponential decays are not unique. It is possible to discover a model that fits the data well but does not describe the decay process accurately. Bajzer and Prendergast[73] illustrate this fact by showing that multiexponential intensity decays of some single-tryptophan proteins can be described just as well by considering the tryptophan emission quenched by unspecified energy transfer acceptors 'present in or close to the protein matrix' as they are by conformational changes or lifetime distributions.

4.3.3 Maximum Entropy Method

When the decay of fluorophores in locally heterogeneous media are measured, the goal of objective, unambiguous decay analysis is more difficult to achieve. Analyzing such measurements by fitting the data to models selected by the analyst can be risky. If structural nuances are associated with small features in the measured response, those features could be overlooked during fitting to standard distribution functions. The MEM[74,75] is a powerful method for recovering the value and shape of distributed parameters from dynamic spectral data without a priori assumptions about the nature of the parameters.

A linear matrix transformation models the measurement process, as shown in Equation (72)

$$\sum_{p}^{P} \mathrm{h}_{np}\beta_p = \mathrm{g}_n - \xi_n \qquad \text{or} \qquad \mathbf{H}\boldsymbol{\beta} = \mathbf{g} - \boldsymbol{\xi} \tag{72}$$

where $\boldsymbol{\beta}$ is the parameter distribution, e.g. lifetime distribution (Equation 13), $\mathbf{g}$ is the measured response, e.g. donor decay, $\boldsymbol{\xi}$ is the residual vector and $\mathbf{H}$ is the transformation matrix relating the parameter to the measurement. Theoretically, the parameter distribution, $\boldsymbol{\beta}$, could be estimated by solving Equation (72) using matrix inversion methods, but this is impractical for several reasons. First, the sizes of the matrices $\mathbf{H}$, $\boldsymbol{\beta}$ and $\mathbf{g}$ usually prohibit direct solutions. Second, a direct solution would incorporate the influence of the measurement error, $\boldsymbol{\xi}$, into the results. In decay analysis, the transformation, $\mathbf{H}$, is an inverse Laplace transformation. The transformation is ill-conditioned which means that small errors in $\boldsymbol{\xi}$ can lead to large errors in the resulting distribution.

A direct solution also defies the nature of the problem. Theoretically, an infinite number of solutions reproduce the measured response within the limits of the measurement error. The MEM solves Equation (72) by minimizing the information content of the parameter estimate, $S(\boldsymbol{\beta})$, subject to the constraint that the parameter estimate reconstructs the measured data within the limits provided by the measurement error. Equation (73) shows in mathematical notation,

$$\begin{aligned} &\text{maximize} \quad S(\hat{\boldsymbol{\beta}}) = -\sum_{p}^{P} \frac{\hat{\beta}_p}{\beta_0} \log\left(M\frac{\hat{\beta}_p}{\beta_0} - 1\right) \\ &\text{subject to} \quad C(\hat{\boldsymbol{\beta}}) = \sum_{n}^{N} \left(\frac{\mathrm{f}_n - \mathrm{g}_n}{\sigma_n}\right)^2 \end{aligned} \tag{73}$$

where S is the entropy of the distributed parameter, β_0 is the integral of the distributed parameter, σ_n^2 is the variance associated with measuring the nth component of the response and reconstructed data (simulation) vectors, i.e. f_n and g_n, respectively. The simulation is given by Equation (74)

$$\hat{\mathbf{f}} = \mathbf{H}\hat{\boldsymbol{\beta}} \tag{74}$$

The entropy function measures the information content of the parameter vector. Maximizing S, subject to the chi-squared constraint, $C(\beta)$, on the simulation yields the ''simplest'' distribution, i.e. the one that has the lowest information content (highest entropy), from the family of distributions that represent the data within the fitting criterion.

The MEM algorithm published by Reiter[76] uses constrained nonlinear optimization to solve for $\boldsymbol{\beta}$. The algorithm minimizes the entropy iteratively by solving successive quadratic approximations to the problem. This is similar to the approach used by the Levenberg–Marquardt nonlinear least-squares fittings. The difference here is that the solution at each iteration (step) must satisfy the constraints as well as minimize the objective function. The residuals, which form the constraints, are measured by the chi-squared function rather than sum of squares. The algorithm begins with a quadratic approximation to the entropy function and linear approximation to the chi-squared function in terms of the parameters, $\boldsymbol{\beta}$. Equations (75) and (76) show

$$S(\boldsymbol{\beta} + \Delta\boldsymbol{\beta}) \approx S(\boldsymbol{\beta}) + \Delta\boldsymbol{\beta}^{\mathrm{T}}\underline{\nabla S} + \tfrac{1}{2}\Delta\boldsymbol{\beta}^{\mathrm{T}}\underline{\underline{\nabla^2 S}}\Delta\boldsymbol{\beta} \tag{75}$$

$$C(\boldsymbol{\beta} + \Delta\boldsymbol{\beta}) \approx C(\boldsymbol{\beta}) + \Delta\boldsymbol{\beta}^{\mathrm{T}}\underline{\nabla C} \tag{76}$$

where S is the entropy function, $\boldsymbol{\beta} + \Delta\boldsymbol{\beta}$ is the updated parameter vector, $\underline{\nabla S}$ is the entropy gradient (derivative with respect to the parameter elements) and $\underline{\underline{\nabla^2 S}}$ is the entropy Hessian. The Hessian is a matrix comprised of the second derivatives of S with respect to β on the diagonal and the partial derivatives with respect to β_i and β_j on the off-diagonals. C and $\underline{\nabla C}$ represent the value and derivative of the chi-squared function respectively. To minimize S subject to constraints, C, we combine S and C via a Lagrange multiplier, q. Equations (77) and (78) show

$$L = S - qC \tag{77}$$

$$L(\boldsymbol{\beta} + \Delta\boldsymbol{\beta}) \approx L(\boldsymbol{\beta}) + \Delta\boldsymbol{\beta}^{\mathrm{T}}\underline{\nabla L} + \Delta\boldsymbol{\beta}^{\mathrm{T}}\underline{\underline{\nabla^2 L}}\Delta\boldsymbol{\beta} \tag{78}$$

S is maximized and C satisfied when $\partial L/\partial\beta$ and $\partial L/\partial q$, defined in Equations (79) and (80), are zero.

$$\frac{\partial L}{\partial \boldsymbol{\beta}} = \underline{\nabla L} + \underline{\underline{\nabla^2 L}}\Delta\boldsymbol{\beta} = \underline{\nabla S} - q\underline{\nabla C} + \underline{\underline{\nabla^2 L}}\Delta\boldsymbol{\beta} = 0 \tag{79}$$

$$\frac{\partial L}{\partial q} = C + \Delta\boldsymbol{\beta}^{\mathrm{T}}\underline{\nabla C} \tag{80}$$

Combining these two conditions yields a system of simultaneous linear equations, as shown in Equation (81)

$$\begin{matrix} \underline{\underline{\nabla^2 L}} & -\underline{\nabla C} & \Delta\boldsymbol{\beta} \\ -\underline{\nabla C^{\mathrm{T}}} & 0 & \mathrm{q} \end{matrix} = \begin{matrix} -\underline{\nabla \mathrm{S}} \\ C \end{matrix} \tag{81}$$

The Hessian matrix, $\underline{\underline{\nabla^2 L}}$, and gradients, $\underline{\nabla C}$ and $\underline{\nabla S}$, can be very large. They can be condensed by re-expressing these quantities in terms of some convenient coordinate axes, e.g. the products of the derivatives and the parameter distribution, so that $\Delta\boldsymbol{\beta}$ can be determined using standard methods for solving simultaneous equations. The parameter vector is updated using the increment shown in Equation (82)

$$\hat{\boldsymbol{\beta}} = \boldsymbol{\beta} + \Delta\boldsymbol{\beta} \tag{82}$$

In some cases, the increment will be so large, the updated parameter will not be within the region prescribed by the entropy and constraint approximations, i.e. Equations (75) and (76). In such cases, a smaller step replaces the solution of Equation (81). This process is repeated until the convergence criteria are met.

Hypothetically, the entropy and chi-squared gradients are perpendicular at convergence. In practice, this condition may be difficult to achieve. Convergence criteria based on the chi-squared function can produce satisfactory results. The response model for the decay is given by Equation (83)

$$\mathbf{g} = \sum_{p}^{P} \beta_p \mathrm{e}^{-\lambda_p \mathbf{t}} \tag{83}$$

where λ_p is the decay rate associated with the pth element of the parameter distribution, β_p.

4.3.4 Multivariate Frequency-domain Decay Analysis

When the decay of a mixture of fluorophores is governed by first-order kinetics, the emission response to excitation at modulation frequency w is given by the Fourier transform of the time domain solution (see Equation 15). Specifically, as shown by Equation (84)

$$\mathbf{z}(\mathrm{t}) = \mathbf{W}\mathbf{O}\mathrm{e}^{-i(w\mathrm{t}\mathbf{I}+\mathbf{\Phi})}\mathbf{W}^{-1}\mathbf{z}_0 \tag{84}$$

where $\mathbf{W}$, $\mathbf{W}^{-1}$ and $\mathbf{z}_0$ have the same definitions as in the time domain solution, $\mathbf{O}$ is a diagonal matrix of signal amplitudes, $\mathrm{m}_{ii} = \mathrm{m}_{\mathrm{ex}}/(w^2 + \lambda_i^2)^{1/2}$, and $\mathrm{e}^{i\mathbf{\Phi}}$ is a matrix that has the complex phases of the observed signals on the diagonal. Each element of $\mathbf{z}$ is an oscillation that is demodulated and phase shifted relative to the excitation function. Writing this solution as the Fourier transform of the impulse response we have Equation (85)

$$\mathbf{z}(\mathrm{t}) = \tilde{\mathbf{z}}(w)\mathrm{e}^{iwt} \tag{85}$$

where $\tilde{\mathbf{z}}$ represents the complex Fourier transform coefficients of $\mathbf{z}(\mathrm{t})$ at frequency w.

The Fourier transform of impulse response also is prominent in the Fourier transform of the kinetic equation. It is the product of the decay transform and the complex frequency adjusted for the initial conditions, as shown in Equation (86)

$$\frac{\mathrm{d}\tilde{\mathbf{z}}}{\mathrm{dt}} = \mathbf{K}\tilde{\mathbf{z}} = iw\tilde{\mathbf{z}} - \mathbf{z}_0 \tag{86}$$

This means that at each modulation frequency, the frequency-domain decay coefficients, $\tilde{\mathbf{z}}$, are linear functions of the photokinetics transfer matrix. Sugar[77] showed that when the initial conditions are available, $\mathbf{K}$ could be fit directly to experimental frequency-domain decay data.

When Equation (86) is expanded to multiple modulation frequencies, it becomes a system of linear equations, as shown in Equation (87)

$$\mathbf{K}\mathbf{Z}^{\mathrm{T}} = \mathbf{Z}^{\mathrm{T}}\mathbf{\Omega} - \mathbf{Z}_0^{\mathrm{T}} \tag{87}$$

where $\mathbf{Z}$ and $\mathbf{Z}_0$ are matrices constructed from the values of $\tilde{\mathbf{z}}$ and $\mathbf{z}_0$ measured at all the modulation frequencies (the rows of $\mathbf{Z}_0$ are identical). $\mathbf{\Omega}$ is a diagonal matrix of complex modulation frequencies, $\imath w_l$ $(l = 1 : L)$. As long as the number of frequencies, L, is greater than the number of emitting sample components, $\mathbf{K}$ becomes the unknown in an overdetermined system of equations constructed from the complex part of Equation (87). Neal[78] showed that $\mathbf{K}$ is easily calculated from Equation (88) without fitting.

$$\widehat{\mathbf{K}} = (\mathbf{Z}^{\mathrm{T}}\Omega)_{\mathrm{imag}}\mathbf{Z}^{+}_{\mathrm{imag}} \tag{88}$$

The initial intensities can be calculated by using $\mathbf{K}$ in a rearrangement of Equation (87), to give Equation (89)

$$\mathbf{Z}_0^{\mathrm{T}} = \mathbf{Z}^{\mathrm{T}}\mathbf{\Omega} - \mathbf{K}\mathbf{Z}^{\mathrm{T}} \tag{89}$$

4.3.5 Application of Decay Analysis Methods

The global analysis approach is so general that it can be applied with equal facility to dynamic absorbance data, fluorescence lifetime determinations, determination of excited state kinetics and rotational diffusion coefficients. The primary limitations of global analysis are the fact that the analyst must select the photokinetic model to be used in the fit and the limited number of distribution functions that can be used to model the decay.

The MEM has become the standard complement to global/nonlinear least-squares analysis. The MEM recovers a lifetime distribution from fluorescence decays without input from the analyst regarding the number of components or shape of the distribution. In this sense, the method is model independent. It is important to remember that the generalized exponential model embodied by the MEM (Equation 74) does not describe all types of emission decay. For example, fluorophores in polymers and other viscous, anisotropic media emit decays better characterized by stretched exponentials.[79] Decays of fluorophores subjected to excited state reactions are not always amenable to MEM. Decay components can be characterized by negative pre-exponentials (from negative values of $\mathbf{W}$ in Equation 15). The classical MEM program cannot recover distributions that have negative values because the entropy function does not exist in the domain of negative numbers. Newer versions that address this limitation have been described,[80] but are not as widely distributed as the classic version. This limitation also applies to the analysis of anisotropy decays using the MEM. MEM can reveal unusual features in rotational correlation time distributions and improve the 'goodness of fit' criteria. The analyst must use some other method to determine if the anisotropy decay components are associated with negative pre-exponentials.

The MFDA method also is model-independent in the sense that the analyst need not select the number of

Figure 20 MFDA of emission of pyrene in SDS micelles. The spectra (a) and frequency-domain decays (not shown) of three components: self-associated monomers, $\mathbf{M}_1$ (solid lines); sequestered monomers, $\mathbf{M}_2$ (dotted line); and excimers, X (dash-dotted lines) were resolved from the emission decay matrix (not shown). The photokinetic transfer matrix, **K**, is calculated from the frequency domain decays. The nonzero off-diagonals of **K** indicate a photokinetic mechanism (c). The relative initial intensity vector, $\mathbf{y}_0$, is the scaled average of the initial fluorescence intensity at each modulation frequency (b). (Reproduced by permission of the American Chemical Society from Neal.[78])

system parameters to be determined. MFDA results are not subjective because they are calculated from the measured data without reference to simulated data. Here again, it is important to recognize that there are model limitations inherent in the formalism on which the algorithm is based. MFDA treats decay data as if it were produced by first-order processes, whether they were or not. The MFDA formalism also includes the assumption that a pure decay for each component has been isolated prior to the analysis. The results of analysis of pyrene and pyrene excimer fluorescence decay in surfactant micelles by MFDA are illustrated in Figure 20.

The details of measurement protocols such as the signal-to-noise ratio, sampling rate and sampling cut-off can have significant consequences on all decay analysis methods. If the decay is inadequately sampled or acquired with an insufficient signal-to-noise ratio, the accuracy as well as the precision of the analysis may be unacceptable. James and Ware[81] have studied the signal-to-noise ratio required to distinguish lifetime distributions from closely spaced discrete lifetimes using time-correlated single photon counting. Shaver and McGown[82,83] have studied the impact of measurement conditions on MEM in frequency-domain measurements. Clearly, special attention should be given to the details of the decay acquisition when analysis results are interpreted.[84,85] A list of selected decay analysis applications is provided in Table 2.[14,15,22,31,42,86–98]

4.4 Matrix Factorization Methods

4.4.1 Self-modeling Curve Resolution

Self-modeling curve resolution (SMCR)[99,100] is a numerical procedure for determining the responses of individual components from matrix-formatted data. SMCR resolves

component responses from bilinear matrices, i.e. matrices that are sums of the outer products of the component responses to experimental variables. For example, the steady-state fluorescence EEM is the sum of the outer products of the excitation and emission spectra of the sample components, so it is an example of a bilinear matrix. The matrix can be written as Equation (90)

$$\mathbf{M} = \sum_{k}^{K} \mathbf{M}_k = \sum_{k}^{K} \gamma_k \mathbf{x}_k \mathbf{y}_k^{\mathrm{T}} = \mathbf{X}\boldsymbol{\Gamma}\mathbf{Y}^{\mathrm{T}} \tag{90}$$

where K is the number of sample components, $\mathbf{M}_k$ is the EEM of the kth component and the columns of $\mathbf{X}$ and $\mathbf{Y}$ are the component excitation and emission spectra, respectively. Consequently, each column and row of this matrix is a linear combination of the excitation or emission spectra of the sample components.

The columns and rows of every matrix $\mathbf{M}$ can be expressed as combinations of orthogonal vectors, as shown in Equation (91)

$$\mathbf{M} = \sum_{k}^{K} \sigma_k \mathbf{u}_k \mathbf{v}_k^{\mathrm{T}} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^{\mathrm{T}} \tag{91}$$

where the columns of the $N \times P$ matrix $\mathbf{U}$ are orthonormal (i.e. $\mathbf{U}'\mathbf{U} = \mathbf{I}$, the identity matrix) basis vectors for the column space of $\mathbf{M}$, the columns of the $M \times P$ matrix $\mathbf{V}$ are orthonormal basis vectors for the row space of $\mathbf{M}$ and P is the smaller of the two matrix dimensions N and M. The matrix $\boldsymbol{\Sigma}$ is diagonal; the magnitude of each nonzero element, σ_k, reflects the contribution of the product $\mathbf{u}_k\mathbf{v}_k^{\mathrm{T}}$ to the variance of $\mathbf{M}$. The factorization of $\mathbf{M}$ into orthogonal vectors is called the singular value decomposition. The number of basis vectors is equal to P (the smaller matrix dimension) rather than K (the number of fluorophores) because of the superposition of measurement noise on the instrument response. However, only K of these basis vectors describe variance associated with the spectral signal. The remaining $P-K$ vectors describe noise and should be eliminated from the matrices $\mathbf{U}$ and $\mathbf{V}$ prior to further analysis. When the number of fluorescent components is not known prior to the analysis, K can be estimated using a number of statistical and signal processing techniques.[101,102] The determination of K is called rank estimation. This topic is discussed in more detail in section 5.2. From this point, $\mathbf{U}$ and $\mathbf{V}$ represent truncated $N \times K$ and $M \times K$ matrices, respectively.

The data matrix $\mathbf{M}$ is the product of $\mathbf{U}$, $\mathbf{S}$, and $\mathbf{V}$, but $\mathbf{U}$ and $\mathbf{V}$ are inconsistent with physically meaningful spectral responses. Physically meaningful responses (e.g. spectra and concentrations) must be non-negative. These conditions rarely are met by the columns of $\mathbf{U}$ and $\mathbf{V}$. However, since the columns of $\mathbf{M}$ are combinations of both the columns of $\mathbf{U}$ and the columns of $\mathbf{X}$, $\mathbf{U}$ and $\mathbf{X}$ must be linear combinations of each other. Similarly, $\mathbf{V}$ and $\mathbf{Y}$ are linear combinations of each other. Consequently, it is possible to reconstruct $\mathbf{X}$ and $\mathbf{Y}$ from $\mathbf{U}$ and $\mathbf{V}$, respectively. The column vectors $\mathbf{X}$ are constructed by combining multiples of the columns of $\mathbf{U}$ so that they form vectors that meet the mathematical conditions on physically realistic responses. The matrix $\mathbf{Y}$ is similarly reconstructed from $\mathbf{V}$, but with the additional constraint that the product of $\mathbf{X}$, $\boldsymbol{\Gamma}$ and $\mathbf{Y}$ continue to equal $\mathbf{M}$. In many cases, the non-negativity and other constraints do not define unique values for $\mathbf{X}$ and $\mathbf{Y}$. Neal et al.[100] described a variant of the original SMCR algorithm which factors $\mathbf{M}$ into a single solution for $\mathbf{X}$ and $\mathbf{Y}$. This factorization of $\mathbf{M}$ is based on the idea that if the rows and columns are transformed independently, the diagonality of concentration factor matrix, $\boldsymbol{\Gamma}$, reflects the quality of the solution. Specifically, Equation (92) shows

$$\mathbf{M} = \mathbf{U}\boldsymbol{\Pi}\boldsymbol{\Pi}^{-1}\boldsymbol{\Sigma}\boldsymbol{\Theta}^{-\mathrm{T}}\boldsymbol{\Theta}\mathbf{V}^{\mathrm{T}} = \hat{\mathbf{X}}\hat{\boldsymbol{\Gamma}}\hat{\mathbf{Y}}^{\mathrm{T}} \tag{92}$$

where the circumflexes indicate estimated values. The steps of the factorization are:

- Calculate **U**, **Σ** and **V** from **M** by singular value decomposition.
- Construct non-negative estimates of **X** and **Y** using transformation matrices, **Π** and **Θ**: $\widehat{\mathbf{X}} = \mathbf{U\Pi}$ and $\widehat{\mathbf{Y}} = \mathbf{V}\Theta$.
- Estimate **Γ** from the estimates of **X** and **Y**: $\widehat{\mathbf{\Gamma}} = \mathbf{\Pi}^{-1}\mathbf{\Sigma\Theta}^{-T}$.
- Minimize the off-diagonal elements of $\widehat{\mathbf{\Gamma}}$.

The values of **Π** and **Θ** that diagonalize the concentration factor matrix, $\widehat{\mathbf{\Gamma}}$ are determined by constrained minimization of the sum of the squared off-diagonals of $\widehat{\mathbf{\Gamma}}$. As this sum is reduced, the **U** and **V** are reconciled to the mathematical constraints on spectral responses, transforming them to $\widehat{\mathbf{X}}$ and $\widehat{\mathbf{Y}}$. The accuracy of the transformation depends on several factors including the matrix signal-to-noise ratio and the similarity of the component spectral responses that constitute **X** and **Y**. High signal-to-noise ratio and dissimilar component responses promote accurate transformations.

4.4.2 Evolving Factor Analysis

Evolving factor analysis (EFA)[103] is a numerical procedure for partitioning matrices when some features of the profile of one of the responses are known. For example, when the eluent from a chromatographic or electrophoretic separation is monitored spectroscopically, it is known that each system component will have a single maximum in its elution profile. EFA-type algorithms operate on the principle that when the part of the profile associated with a single component is deleted from the matrix the rank of the matrix is reduced by one. In an early EFA algorithm,[103] the eigenvalues of sub-matrices constructed by successively adding rows starting from the beginning of the acquisition are compared with eigenvalues of sub-matrices constructed by successively including rows starting from the end of the acquisition. Plots of the eigenvalues were combined to produce crude elution profiles.

Today, more efficient algorithms are used. For example,[104] the basic structure for the data collected when separations or kinetics are monitored spectroscopically is given by Equation (93)

$$\underline{\underline{A}} = \sum_{k}^{K} \varepsilon_{\cdot k} c_{\cdot k}^{\mathrm{T}} = \mathbf{EC}^{\mathrm{T}} \tag{93}$$

where the columns of **E** represent the absorbance spectra (molar absorptivities times pathlength), and the columns of **C** represent the time evolution of the sample components, respectively. When the rows associated with the kth component are set aside, principal components analysis of the remaining matrix is given by Equation (94)

$$\underline{\underline{A}}^{\circ} = \mathbf{Q}^{\circ}(\mathbf{V}^{\circ})^{\mathrm{T}} \tag{94}$$

The columns of $\mathbf{V}^{\circ}$ are the singular vectors ($\mathbf{Q} = \mathbf{U\Sigma}$) of the time profiles of the remaining spectra. Since the time evolution of the kth compound is not described by $\mathbf{V}^{\circ}$, any part of the rows of **A** that is not described by $\mathbf{V}^{\circ}$ must be the part of the kth component profile. The response of the deleted compound is given by Equation (95)

$$\underline{\underline{A}}(\mathbf{I} - \mathbf{V}^{\circ}(\mathbf{V}^{\circ})^{\mathrm{T}}) = \underline{\underline{A}}_{k} = \boldsymbol{\varepsilon}_{\cdot k}^{+}\mathbf{c}_{\cdot k}^{\mathrm{T}} \tag{95}$$

where $\boldsymbol{\varepsilon}_{\cdot k}^{+}$ represents the part of the kth component spectrum that is uncorrelated with the other spectra and $\mathbf{c}_{\cdot k}$ is the time profile of the kth component. This procedure is repeated for all K components of the sample and the recovered time profiles are used to calculate the spectra of the sample components. Equation (96) shows

$$\mathbf{E} = \underline{\underline{A}}\mathbf{C}^{+} \tag{96}$$

where $\mathbf{C}^{+}$ is the pseudoinverse of **C**.

4.4.3 Generalized Rank Annihilation Method

The generalized rank annihilation method (GRAM) simultaneously factors two matrices, e.g. sample and calibration matrix, without the potential ambiguity of SMCR or the EFA requirement for unique maxima in the component profiles. The sample and calibration standard matrices, **M** and **N**, given in Equations (97) and (98), are combinations of the same row and column basis vectors, e.g. fluorescence excitation and emission spectra.

$$\mathbf{M} = \mathbf{X}\mathbf{\Gamma}_{\mathrm{M}}\mathbf{Y}^{\mathrm{T}} \tag{97}$$

$$\mathbf{N} = \mathbf{X}\mathbf{\Gamma}_{\mathrm{N}}\mathbf{Y}^{\mathrm{T}} \tag{98}$$

$\mathbf{\Gamma}_{\mathrm{M}}$ and $\mathbf{\Gamma}_{\mathrm{N}}$ are diagonal concentration factor matrices. Lorber[105] realized that the component responses, **X** and **Y**, could be determined by combining Equations (97) and (98) into a single generalized eigenvalue problem giving Equation (99)

$$\mathbf{MZ\Lambda} = \mathbf{NZ} \tag{99}$$

where $\mathbf{Z} = \mathbf{Y}^{+}$ and $\mathbf{\Lambda} = \mathbf{\Gamma}_{\mathrm{N}}\mathbf{\Gamma}_{\mathrm{M}}^{-1}$. The eigenvectors of $\mathbf{N}^{-1}\mathbf{M}$ are the columns of the pseudoinverse of the matrix of component responses, **Y**. The column response can be calculated directly from $\mathbf{Y}^{+}$ and **Λ**, as shown in Equation (100)

$$\mathbf{X} = \mathbf{MZ\Lambda} \tag{100}$$

Figure 21 Resolution of pure excitation (a) and emission (b) spectra of *trans*-1-(2-naphthyl)-2-phenylethene conformers resolved from mixture spectra by SMCR. Principal component loadings (top) of mixture spectra fall on single lines indicating two components. The principal components (middle) are linear combinations of the component spectra. The spectra (bottom) are reconstructed from combinations of the singular vectors. (Reproduced by permission of the American Chemcial Society from Saltiel et al.[108])

The original algorithm has been revised to accommodate rectangular matrices and calibration matrices that do not include all the components in the sample matrix.[106]

The acquisition need not stop with two matrices. For example, the emission-decay matrix could be acquired as a function of excitation wavelength. The result is a three-way matrix given by Equations (101) and (102)

$$d_{nmp} = \sum_{k}^{K} x_{nk} y_{mk} z_{pk} + e_{nmp} \tag{101}$$

$$\mathbf{D} = \mathbf{X} \otimes \mathbf{Y} \otimes \mathbf{Z} \tag{102}$$

The generalized multiplication operator, $\otimes$, combines three column matrices into the three-way matrix. If the number of sample components that absorb and emit are the same, the spectra and decays of all K components can be recovered from the three-way matrix. The model embodied in Equation (101) corresponds to a system in which all the components respond independently to all three sets of experimental variables, e.g. excitation wavelength, emission wavelength, and time. Direct trilinear decomposition (DTD),[107] a variant of GRAM, reduces the P matrix slices to a single pair and calculates $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ without ambiguity using the approach described above.

4.4.4 Application of Matrix Factorization

Spectrometric data matrices are acquired regularly, if not routinely. Multiple wavelength kinetic measurements are used to study dynamic processes in multicomponent systems from photosynthetic reaction centers to polymers. In most cases, these matrices are analyzed using globals or a principal components based variant that fits the decay factors to user specified decay models. SMCR, GRAM and DTD have not been used as widely. GRAM and DTD are projection methods and they are not always robust. On the other hand, GRAM factors matrices without the rotational ambiguity of SMCR. Therefore, it is useful to acquire a second matrix under related conditions when possible. Figure 21 illustrates the *trans*-1-(2-naphthyl)-2-phenyethene conformer spectra resolved by SMCR of quenched mixture spectra arranged in matrix format.[108] Moderate measurement errors can cause dramatic oscillations in the results. Alternating trilinear decomposition[109] is an optimization routine that implements the DTD resolution less stringently and with more stable results. The requirement that the analyst has two samples containing different relative ratios of the same components also may be limiting the use of this method. A second matrix has been generated instrumentally using phase-resolved detection[110] and using perpendicular emission polarizer settings.[111] Theoretically, it should also be possible to produce the second matrix by adding a selective quencher to the sample. A short list of matrix factorization applications is provided in Table 3.[104,111–126]

5 ERROR ANALYSIS AND RESULT VALIDATION

5.1 Parameter Confidence Intervals

The precision of linear parameters recovered by regression methods can be determined from the variance of the independent variables.[127] For a linear regression Equation (103) shows

$$\hat{\mathbf{B}}_{\text{sample}} = \mathbf{F}^{-}\mathbf{G}_{\text{sample}} \tag{103}$$

The variances of the elements on each column of the parameter matrix **B** are given by the diagonal elements of the following matrix, as shown in Equation (104)

$$_{b_{\cdot i}}\boldsymbol{\Psi} = \mathrm{var}(\mathbf{F}^{-}\mathbf{g}_{\cdot i}) = \mathbf{F}^{-}\mathbf{g}_{\cdot i}(\mathbf{F}^{-}\mathbf{g}_{\cdot i})^{\mathrm{T}} = \mathbf{F}^{-}\mathbf{g}_{\cdot i}\mathbf{g}_{\cdot i}^{\mathrm{T}}(\mathbf{F}^{-})^{\mathrm{T}} \quad (104)$$

In other words, the variance of parameter β_{21} would be $_{b_{\cdot 1}}\boldsymbol{\Psi}_{22}$. It is important to mean center **F** and **G**, that is subtract the column average from every element on a column, prior to calculating the variance matrices. The off-diagonal elements of $\boldsymbol{\Psi}$, i.e. ψ_{ij}, are the covariances of the parameters which reflect the impact of variation in parameter *i* on the variance of parameter *j*.

The precision of parameters recovered by nonlinear least-squares also are functions of the variances of the parameters. Rather than mean center **F** and **G** to calculate $\boldsymbol{\Psi}$, the variance–covariance matrix of the derivatives of the weighted residuals at the minimum is a convenient estimate of the variance in the parameters. The variance–covariance matrix is given by Equation (105)

$$_{\mathbf{J}}\boldsymbol{\Psi} = (\mathbf{J}^{\mathrm{T}}\mathbf{J})^{-1} \quad (105)$$

The square roots of the diagonal elements of $_{\mathbf{J}}\boldsymbol{\Psi}$ provide an estimate for the standard error of the parameters. For many applications of nonlinear least-squares these estimates are sufficient, but they are imperfect. They are the variances in the linear approximation of the parameters. (Remember, there is no contribution from the second derivatives in Equation 64.) The estimate also assumes that the parameters are completely uncorrelated, i.e. orthogonal. Unless all the off-diagonals of $\boldsymbol{\Psi}$ are zero, this criterion is not satisfied. Error estimates without these assumptions can be calculated, for example, using Monte Carlo methods, but they are computationally expensive and are generally reserved for exceptional circumstances.

5.2 Rank Estimation

The first step in the analysis of matrix-formatted spectral data, that is PCR, PLS, MFDA, SMCR, EFA, GRAM and DTD, is the determination of the number of chromophores or fluorophores that give rise to the observed matrix. Measurement errors superimposed on the fluorescence signal inflate the rank of experimental matrices to the smaller of the matrix dimensions. The singular vectors and singular values are ordered by magnitude, so that the first matrix component, i.e. $\mathbf{u}_{\cdot 1}s_{11}\mathbf{v}_{\cdot 1}^{\mathrm{T}}$, describes the largest fraction of the matrix variance and the last component, $\mathbf{u}_{\cdot P}s_{PP}\mathbf{v}_{\cdot P}^{\mathrm{T}}$, describes the smallest. The largest matrix components describe the variance associated with the spectral response, the remaining components describe the measurement error. In the case of high signal-to-noise ratios and moderate spectral overlap, the difference between primary (spectral) and secondary (noise) matrix components is clear in the magnitudes of the singular values. In the case of low signal-to-noise ratios and severely overlapped component spectra, determination of the number of spectral components, i.e. the pseudorank, can be a difficult problem. Determination of the optimal number of matrix factors is critical to accurate analysis. If the number of factors is too low, the model will be inaccurate because responses produced by the sample of interest end up in the residuals. If the number of factors is too high, noise is incorporated into the model, increasing the error of prediction or in the parameters.

There are two types of rank indicators. Some methods compare the variance of the matrix components, i.e. the relative magnitudes of the σ_{ii}. Other methods compare the frequency content of the singular vectors, capitalizing on the predominance of high frequency signal components in measurement noise. The wisest course is to use the consensus result of several methods. The most rigorous method for determining the number of factors contributing to a model is cross-validation.[101] The optimal number of factors is the number that produces the smallest average prediction error when the matrix is reconstructed using column factors generated by systematically removing the columns of the matrix one at a time. Other variance-based methods include reduced eigenvectors, the indicator function and F-tests.[128] The autocorrelation function[129] (see discussion below) and the Fourier coefficient method[102] estimate the rank by determining the presence of non-random variance (low frequency signals) in the singular vectors.

5.3 Residual Analysis

Other measures of fit quality are based on the residuals. The chi-squared function measures the residuals relative to the measurement precision. The reduced chi-squared is given by Equation (106)

$$\chi^2 = \frac{1}{\nu}\sum_{i}^{n}\left(\frac{\mathrm{f}_i - \mathrm{g}(\alpha_i)}{\sigma_i}\right)^2 \quad (106)$$

where ν is the number of degrees of freedom associated with the residuals, i.e. the number of parameters subtracted from the number of all but one of the measured values. The reduced chi-squared is close to unity when the data have been fitted adequately.

The size of the residuals is not the only indicator of fit quality. The residuals also should distribute randomly around the origin when the measurement error is normally distributed; systematic errors indicate that the data, **f**, are not well modeled by the simulation, **g**. The autocorrelation of the residuals is a simple measure of the presence of structure in the residuals. It is

given by the sum of residual covariances, as shown in Equation (107)

$$\zeta_k = \sum_{i=1}^{N-k} \xi_i \xi_{i+k} \tag{107}$$

The analyst chooses the lag, k. Autocorrelations calculated using k equal to 1 and 2 are common. Visual inspection of plots of ξ_i vs ξ_{i+k} also show indications of trends in residuals. The autocorrelation function can also be used for rank estimation by determining the presence of systematic variance in matrix factors.

5.4 Stability

The stability of a calculation is primarily a product of the algorithm used to perform the calculation. Sometimes, a procedure that is conceptually straightforward inflates computer round-off errors to an unacceptably high level. The best insurance against this is to use software based on well-designed and tested algorithms. The stability of a transformation can be determined from the condition number of the associated matrix.[130] For Equation (103), the condition number is given by Equation (108)

$$\text{cond}(\mathbf{F}) = \frac{\sigma_{11}}{\sigma_{KK}} \tag{108}$$

where σ_{KK} and σ_{11} are the last and first singular values of **F**. When the condition number is small, e.g close to unity, the matrix is well-conditioned. Transformations of well-conditioned matrices are stable and not subject to error inflation. If it is found that a data set is ill-conditioned, the analyst should attempt to use variable settings which will improve the condition number. A complete discussion of this topic is beyond the scope of this article, and can be found in references that discuss multivariate calibration in detail.

6 SOFTWARE

Encoding data analysis algorithms can be time-consuming. Fortunately, programs for most of the methods described in this article are available commercially. The names and distributors of the programs are given in the referenced citation. One alternative to buying the programs is to purchase a programming environment that has basic mathematical and statistical operations encoded already. This will reduce the time and effort to encode these algorithms significantly. Several software packages meet this criterion. They vary substantially in price and function. MATLAB (The MathWorks, Natick, MA) is a general-purpose programming language with graphics that is optimized for matrix computations. Extensive toolboxes that have specialized functions for various applications, e.g. signal processing and image analysis, are available. GRAMs/32 (Galactic Industries, Salem, NH) is a package designed specifically for acquisition and analysis of spectral data. The GRAMS environment includes graphics and many pre-programmed functions to simplify data analysis.

7 FUTURE DEVELOPMENT

As technological advances facilitate the acquisition of spectrometric data, the amount and complexity of spectral data will continue. The trend toward increasing dimensionality also will continue. Some of the impetus behind these trends comes from the interest in resolving the components of complex interactions in situ. The tendency for fluorophore emission to respond to the experimental variables independently leads to the increased selectivity of multichannel measurements. It is clear that many of the measurements described in this work will be acquired with spatial resolution using microscopes. This means that the data analysis methods described here will be combined with and complicated by image analysis and reconstruction.

The data analysis methods, specifically generalized rank annihilation and DTD which recover component responses without unambiguity, will continue to be developed and eventually find wide use. Neural networks have not been widely used to analyze absorbance or fluorescence, but they hold promise as multivariate calibration and pattern recognition devices. In pattern recognition devices, neural networks will be used to identify characteristic signals (fingerprints) in complex data sets. In calibration, neural networks can be expected to compensate for strongly correlated variables and matrix effects and may eventually facilitate calibration transfer across spectrometers.

ACKNOWLEDGMENTS

The author's sincere thanks go to Brad Rowe and Linda Staib for their excellent and timely assistance in the preparation of this manuscript.

LIST OF SYMBOLS

The following list is not exhaustive, but contains the main quantities discussed in this article.

$A, \underline{A}, \underline{\underline{A}}$	absorbance	log of ratio of transmitted to incident light, Scalar quantity commonly designated by capital
α_f	response parameter	fluorescence intensity decay pre-exponential
α_c	response parameter	fluorescence anisotropy decay pre-exponential
α_d	response parameter	fluorescence energy transfer decay pre-exponential
b	optical pathlength	distance traveled by light during measurement
β $\boldsymbol{\beta}$, $\mathbf{B}$	response parameters	e.g. sample component concentrations
c, $\mathbf{c}$, $\mathbf{C}$	molar concentration	moles of substance per liter of solution
γ, $\boldsymbol{\gamma}$, $\boldsymbol{\Gamma}$	concentration factor	relative intensity of sample components
d	distance	donor–acceptor distance. Typically represented by r
δ	Dirac function	infinitely narrow pulse
$\mathbf{D}$	data matrix	wavelength–time matrix
D	diffusion coefficient	measure of fluorophore rotation. Scalar quantity commonly designated by capital
D_F	Forster distance	distance of acceptor from donor at which emissive rate and energy transfer rate are equal. Typically represented by R_0. Scalar quantity commonly designated by capital
e	excitation function	e.g. laser pulse for time-resolved measurements
ε, $\boldsymbol{\varepsilon}$, $\mathbf{E}$	molar absorptivity	nominal absorbance of 1 molar solution through 1 cm pathlength
ξ, $\boldsymbol{\xi}$, $\boldsymbol{\Xi}$	residuals	difference between experimental data and simulation
f, $\mathbf{f}$, $\mathbf{F}$	experimental variable	e.g. concentration, time
$\mathbf{g}$	generic instrument model	e.g. fluorescence intensity decay
$\mathbf{H}$	Hessian matrix	matrix of second derivatives
		linear transformation matrix
$I, \underline{I}, \underline{\underline{I}}$	intensity	light intensity. Scalar quantity commonly designated by capital
$I_f, \underline{I_f}, \underline{\underline{I_f}}$	fluorescence intensity	intensity of fluorescence emitted. Scalar quantity commonly designated by capital
$I_\parallel$	parallel polarized intensity	intensity of parallel polarized light. Scalar quantity commonly designated by capital
$I_\perp$	perpendicular polarized intensity	intensity of perpendicular polarized light. Scalar quantity commonly designated by capital
I_I	incident intensity	intensity of incident light. Scalar quantity commonly designated by capital
I_D	donor intensity	intensity of fluorescence emitted by energy transfer donor in the absence of acceptor. Scalar quantity commonly designated by capital
I_{DA}	energy transfer intensity	intensity of fluorescence emitted by energy transfer donor in the presence of acceptor. Scalar quantity commonly designated by capital
I_T	transmitted intensity	intensity of transmitted light. Scalar quantity commonly designated by capital
I_Q	quenched intensity	fluorescence intensity in the presence of quencher. Scalar quantity commonly designated by capital
J	overlap integral	measure of overlap in donor emission and acceptor excitation spectra

$\mathbf{J}$	Jacobian matrix	matrix of first derivatives
k_A	absorption rate	rate of photon absorption
k_f	emissive rate	rate of fluorescence photon emission
k_{ET}	energy transfer rate	rate of excitation energy transfer from donor to acceptor
k_q	bimolecular quenching constant	
κ		orientation of energy transfer donor–acceptor pair
K_Q	generic quenching constant	
$\mathbf{K}$	photokinetic transfer matrix	
$L, \underline{L}$	Lagrange function	objective function in constrained optimization
$\mathbf{L}$	exponential matrix	
λ	wavelength	distance (nm) between maxima in light waves
λ_{ex}	excitation wavelength	distance (nm) between maxima in light waves
λ_{em}	emission wavelength	distance (nm) between maxima in light waves
$\mathbf{\Lambda}$	photokinetic eigenvalues	
m_{ex}	excitation modulation	ratio of oscillating to steady-state component in modulated exciting beam
m_{em}	emission modulation	ratio of oscillating to steady-state component in modulated emission beam
$\mathbf{M}$	excitation–emission matrix	usually represents samples
$\mathbf{N}$	excitation–emission matrix	usually represents standards
n	refractive index	
η	viscosity	
ϑ	degrees of freedom	
$\mathbf{O}$	modulation matrix	ratio of emission and excitation modulations on diagonal
$w, \boldsymbol{\omega}, \mathbf{\Omega}$	angular frequency	$2\pi \times$ frequency of modulated radiation (frequencies on matrix diagonal)
p, $\mathbf{p}$, $\mathbf{P}$	decay sine transform	Imaginary Fourier coefficients of decay
P	polarization	difference in intensity of fluorescence monitored, through parallel and perpendicular polarizers, scaled by sum of polarized intensities. Scalar quantity commonly designated by capital.
ϕ_f	quantum yield	number of fluorescence photons emitted per photon absorbed
φ	emission phase	phase lag of emission produced by sinusoidally modulated excitation
Φ	transition function	length of absorption dipole vector
Ψ	transition function	length of emission dipole vector
$\psi, \boldsymbol{\psi}, \mathbf{\Psi}$	covariance matrix	
q	Lagrange multiplier	modifies constraints in optimization problems
q, $\mathbf{q}$, $\mathbf{Q}$	decay cosine transform	Real Fourier coefficients of decay
r, $\mathbf{r}$, $\mathbf{R}$	anisotropy	difference in intensity of fluorescence monitored, through parallel and perpendicular polarizers, scaled by total emission intensity
R	gas constant	
ρ	residual sum of squares	
s, $\mathbf{s}$, $\mathbf{S}$	simulated response	
$S, \underline{S}, \underline{\underline{S}}$	entropy	regularizing function indicating information content

σ, $\boldsymbol{\sigma}$, $\boldsymbol{\Sigma}$	standard error	diagonal elements of singular value matrix equal square roots of the matrix component variances
ς, $\boldsymbol{\varsigma}$	transition function	cross product of absorption and emission dipoles
t, **t**	time	typically in ns
τ_c	rotational correlation time	average time for rotating fluorophore to trace
τ_D	donor lifetime	average lifetime of energy transfer donor in the absence of acceptor
τ_f	fluorescence lifetime	average lifetime of excited fluorophore
T	transformation	
u, **u**, **U**	column singular vectors	
V	molar volume	
v, **v**, **V**	row singular vectors	
w, **w**, **W**	eigenvectors of **K**	eigenvectors of photokinetic matrix
x, **x**, **X**	excitation spectrum matrix	excitation spectra of components stored on columns
y, **y**, **Y**	emission spectrum matrix	emission spectra of components stored on columns
z, **z**, **Z**	emission decay matrix	decay profiles of components stored on columns
ζ	emission profile

APPENDIX 1: MATRIX ALGEBRA BASICS

Notation

Matrices are denoted by uppercase, boldface Roman and Greek letters, vectors are denoted by lowercase, boldface Roman and Greek letters. Vectors that are columns of a matrix are denoted using the subscripted, lower case boldface matrix variable, i.e. $\mathbf{m}_{\cdot j}$ denotes the jth column of $\mathbf{M}$. Similarly, vectors that are rows of the matrix $\mathbf{M}$, are denoted $\mathbf{m}_{i\cdot}$, where i represents the ith row. The matrix element on row i in column j is denoted m_{ij}. The variable m is a generic reference to any single element of $\mathbf{M}$. Scalar variables that are not drawn from matrices and vectors are denoted by uppercase and lowercase italic Roman and Greek letters. The uppercase variables may be subscripted for identification purposes. For example, I_f is the fluorescence intensity, where as I_0 is the intensity of the incident excitation beam. Complex variables are indicated using a superpositioned tilde, i.e. $\tilde{\mathbf{M}}$. The superpositioned circumflex, i.e. $\hat{\mathbf{M}}$, indicates an estimated value. As usual, superscript -1, e.g. M^{-1}, denotes the matrix inverse, and the superscript capital T denotes the matrix transpose, $\mathbf{M}^T$. The superscript $+$ denotes the pseudoinverse of a matrix, e.g. M^+. The pseudoinverse[14] is a limited inverse, $\mathbf{M}^+\mathbf{M} = \mathbf{I}$, that can be used to solve linear systems when a matrix is has no classical inverse. Left superscripts, e.g. ${}^k\mathbf{m}$, indicate the iteration number in repetitive procedures.

Definitions

1. scalar: single number m
2. vector: sequence of numbers arranged in a column

$$\mathbf{m} = \begin{matrix} m_1 \\ \vdots \\ m_n \end{matrix}$$

3. matrix: sequence of numbers arranged in a table:
   (a) sequence of vectors
   (b) a linear operator, representation of a linear multivariable function

$$\mathbf{M} = \begin{matrix} m_{11} & \cdots & m_{1n} \\ \vdots & \ddots & \vdots \\ m_{m1} & \cdots & m_{mn} \end{matrix} = \begin{matrix} \vdots & \vdots & \vdots \\ \mathbf{m_{\cdot 1}} & \mathbf{m_{\cdot 2}} & \mathbf{m_{\cdot 3}} \\ \vdots & \vdots & \vdots \end{matrix}$$

Special Matrices

1. identity matrix:

$$\mathbf{I} = \begin{matrix} 1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & 1 \end{matrix} \qquad \mathbf{Ib} = \mathbf{b}; \quad \mathbf{AI} = \mathbf{A}$$

2. symmetric matrix:

$$\mathbf{A} = \mathbf{A}^T \quad a_{ij} = a_{ji} \quad \text{for all} \quad i, j$$

3. inverse matrix:*

$$\mathbf{A}^{-1} = \frac{1}{|\mathbf{A}|} \begin{matrix} \mathbf{c_{11}} & \cdots & \mathbf{c_{1n}} \\ \vdots & \ddots & \vdots \\ \mathbf{c_{n1}} & \cdots & \mathbf{c_{nn}} \end{matrix}^T \qquad \mathbf{A^{-1}A} = \mathbf{AA^{-1}} = \mathbf{I}$$

* square matrices only
c_{ij} represents the cofactor of a_{ij}
cofactor of a_{ij} is determinant of $\mathbf{A}$ after row i and column j are deleted

4. pseudoinverse: $\mathbf{A}^+ = \mathbf{V}\boldsymbol{\Sigma}^{-1}\mathbf{U}^T$ (see singular value decomposition below)

$$\mathbf{A}^+\mathbf{A} = \mathbf{I}$$

Operations

1. addition:

$$\begin{matrix} a_1 \\ a_2 \\ a_3 \end{matrix} + \begin{matrix} b_1 \\ b_2 \\ b_3 \end{matrix} = \begin{matrix} a_1 + b_1 \\ a_2 + b_2 \\ a_3 + b_3 \end{matrix} = \begin{matrix} c_1 \\ c_2 \\ c_3 \end{matrix}$$

$$\mathbf{a + b = c} \quad \mathbf{A + B = C}$$

$$\begin{matrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{matrix} + \begin{matrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{matrix} = \begin{matrix} a_{11} + b_{11} & a_{12} + b_{12} \\ a_{21} + b_{21} & a_{22} + b_{22} \end{matrix} = \begin{matrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{matrix}$$

2. subtraction:

$$\begin{matrix} a_1 \\ \vdots \\ a_n \end{matrix} - \begin{matrix} b_1 \\ \vdots \\ b_n \end{matrix} = \begin{matrix} a_1 - b_1 \\ \vdots \\ a_n - b_n \end{matrix} = \begin{matrix} c_1 \\ \vdots \\ c_n \end{matrix}$$

$$\mathbf{a - b = c} \quad \mathbf{A - B = C}$$

3. multiplication:
   (a) scalar multiplication:

$$c \begin{matrix} a_1 \\ a_2 \\ a_3 \end{matrix} = \begin{matrix} ca_1 \\ ca_2 \\ ca_3 \end{matrix} = c\mathbf{a}$$

$$c \begin{matrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{matrix} = \begin{matrix} ca_{11} & ca_{12} \\ ca_{21} & ca_{22} \end{matrix} = c\mathbf{A}$$

   (b) dot (scalar, inner) product:

$$\begin{bmatrix} a_1 & a_2 & a_3 \end{bmatrix} \begin{matrix} b_1 \\ b_2 \\ b_3 \end{matrix} = \sum_{k=1}^{3} a_k b_k = \mathbf{a}^T\mathbf{b}$$

$$(1 \times 3)(3 \times 1) \Longrightarrow 1 \times 1$$

if $\mathbf{a}^T\mathbf{b} = 0$, $\mathbf{a}$, $\mathbf{b}$ are orthogonal
$(\mathbf{a}^T\mathbf{a})^{1/2} = \|\mathbf{a}\|$, vector length

(c) outer product:

$$\begin{matrix} a_1 \\ a_2 \\ a_3 \end{matrix} \begin{bmatrix} b_1 & b_2 & b_3 \end{bmatrix} = \mathbf{ab}^T = \begin{matrix} a_1b_1 & a_1b_2 & a_1b_3 \\ a_2b_1 & a_2b_2 & a_2b_3 \\ a_3b_1 & a_3b_2 & a_3b_3 \end{matrix}$$

$$= \begin{matrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{matrix} = \mathbf{C}$$

$$(3 \times 1)(1 \times 3) \Longrightarrow (3 \times 3)$$

(d) matrix multiplication:

$$\mathbf{AB} = \begin{matrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{matrix} \begin{matrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{matrix}$$

$$= \begin{matrix} \sum_{k=1}^{2} a_{1k}b_{k1} & \sum_{k=1}^{2} a_{1k}b_{k2} \\ \sum_{k=1}^{2} a_{2k}b_{k1} & \sum_{k=1}^{2} a_{2k}b_{k2} \end{matrix}$$

$$= \begin{matrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{matrix} = \mathbf{C}$$

4. Division:

$$\mathbf{A}^{-1}\mathbf{b} = \begin{matrix} a_{11}^{-1} & \cdots & a_{1j}^{-1} & \cdots & a_{1n}^{-1} \\ \vdots & & & & \vdots \\ a_{i1}^{-1} & & \ddots & & a_{in}^{-1} \\ \vdots & & & & \vdots \\ a_{n1}^{-1} & \cdots & a_{nj}^{-1} & \cdots & a_{nn}^{-1} \end{matrix} \begin{matrix} b_1 \\ \vdots \\ b_n \end{matrix}$$

$$= \begin{matrix} \sum_{j}^{n} a_{1j}^{-1}b_j \\ \vdots \\ \sum_{j}^{n} a_{ij}^{-1}b_j \\ \vdots \\ \sum_{j}^{n} a_{nj}^{-1}b_j \end{matrix} = \begin{matrix} c_1 \\ \vdots \\ c_n \end{matrix} = \mathbf{c}$$

or $\mathbf{A}^{+}\mathbf{b} = \mathbf{c}$ if $\mathbf{A}$ is not square

5. matrix transpose:

$$\mathbf{A}^T = \begin{matrix} a_{11} & \cdots & a_{1m} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nm} \end{matrix}$$

6. matrix exponential:

$$e^{\mathbf{A}} = \begin{matrix} v_{11} & \cdots & v_{1n} \\ \vdots & \ddots & \vdots \\ v_{m1} & \cdots & v_{mn} \end{matrix} \begin{matrix} e^{\lambda_{11}} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & e^{\lambda_{nn}} \end{matrix} \begin{matrix} v_{11} & \cdots & v_{1n} \\ \vdots & \ddots & \vdots \\ v_{m1} & \cdots & v_{mn} \end{matrix}^{-1}$$

where $\mathbf{AV} = \mathbf{V\Lambda}$ (see below)
for diagonal $\mathbf{A}$, $\mathbf{V} = \mathbf{I}$

Structure

1. Singular value decomposition:

$$\mathbf{M} = \begin{matrix} u_{11} & \cdots & u_{1k} \\ \vdots & \ddots & \vdots \\ u_{m1} & \cdots & u_{mk} \end{matrix} \begin{matrix} s_{11} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & s_{kk} \end{matrix} \times \begin{matrix} v_{11} & \cdots & v_{1k} \\ \vdots & \ddots & \vdots \\ v_{n1} & \cdots & v_{nk} \end{matrix}^{T} = \mathbf{USV}^T$$

$\mathbf{UU}^T = \mathbf{U}^T\mathbf{U} = \mathbf{I}_m \qquad \mathbf{VV}^T = \mathbf{V}^T\mathbf{V} = \mathbf{I}_n$
$\mathbf{U}$ and $\mathbf{V}$ are orthonormal (orthogonal and normalized to unit length)
if $\mathbf{M}$ is square: $\mathbf{M}^{-1} = \mathbf{VS}^{-1}\mathbf{U}^T$
if $\mathbf{M}$ is not square: $\mathbf{M}^{+} = (\mathbf{M}'\mathbf{M})^{-1}\mathbf{M} = \mathbf{VS}^{-1}\mathbf{U}^T$

2. Eigenanalysis:

$$\mathbf{MV} = \begin{matrix} m_{11} & \cdots & m_{1n} \\ \vdots & \ddots & \vdots \\ m_{m1} & \cdots & m_{mn} \end{matrix} \begin{matrix} v_{11} & \cdots & v_{1k} \\ \vdots & \ddots & \vdots \\ v_{n1} & \cdots & v_{nk} \end{matrix}$$

$$= \begin{matrix} \lambda_{11} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \lambda_{kk} \end{matrix} \begin{matrix} v_{11} & \cdots & v_{1k} \\ \vdots & \ddots & \vdots \\ v_{n1} & \cdots & v_{nk} \end{matrix} = \mathbf{\Lambda V}$$

$$\mathbf{M} = \mathbf{VSV}^{-1}$$

1 BACKGROUND

Gas chromatography (GC; sometimes called gas–liquid chromatography or GLC) has developed from a single successful application for separating volatile carboxylic acids in the early 1950s[1] into a universally accepted chemical measurement tool spanning the disciplines of chemistry, biochemistry, forensics, toxicology, environmental sciences, and others. The development of GC arose in the context of surging interests in electronics and analytical instrumentation in the post-World War II era. A growing reliance then and now upon physical methods for chemical analyses, such as mass spectrometry (MS) or infrared spectrometry, meant that instrumental characterizations of complex mixtures would be difficult to interpret without prefractionating a sample into individual constituents. GC met this requirement for volatile and semivolatile organic compounds. These compounds constitute only a fraction of all organic substances; however, their relative importance in foodstuffs, cosmetics, and medicines, or in some instances as persistent and toxic pollutants in the environment, guaranteed a role for GC in modern analytical methods.

The speed and effectiveness of GC for separating petroleum materials and natural products such as fragrances were recognized early on and led to a widespread demand for commercial instrumentation. Fundamental developments in descriptions of the chromatographic processes and improved methods of operation provided a foundation for the extension of GC into further applications. This resulted in vigorous activity surrounding GC and the number of abstracts exceeded 1800 per annum after only a decade of development.[2] This pace of publication is comparable to that of today, where about 2000 citations per annum can be seen in results from abstracting services.[3] Careful examination of the literature reveals that much of the essential direction and technology had been described by the early 1960s,[4] although refinements and improvements in the technology have continued. During the 1990s, such advances in the principles of the technique have slowed, although new applications or adaptations of GC abound annually.

2 HISTORICAL REVIEW OF GAS CHROMATOGRAPHY DEVELOPMENTS

In the 1950s the use of stationary liquid phases on solid supports for separating substances within a chemical class rapidly became a generally applicable tool for separating complex mixtures of volatile organic compounds, in contrast to the previous use of an uncoated adsorbent.[5] This was particularly effective in the resolution of constituents in natural fragrances and petroleum samples, and the growth of demand for these separations fostered a nascent industry for the commercialization of GC. Consequently, the availability and convenience of GC instruments for scientists promoted worldwide advances in GC practices and in the description of fundamental principles. Early and nearly complete descriptions of the separation processes were made by the late 1950s, using mathematicales models adapted from existing separation methods. Although packed columns were nearly standard items, the advantages of capillary columns were understood and had been tested by 1958.[6]

During the 1960s commercial instrumentation was developed further, assisted by the availability of programmable ovens, an expanded selection of detectors, and other refinements. The four main detectors in use today (flame ionization, electron capture, thermal conductivity, and MS) were described in this period and most detectors were at a comparatively advanced, stable stage of design by the late 1960s. Discussion groups, abstracting services, and journals such as the *Journal of Gas Chromatography* (later, *Journal of Chromatographic Science*) and the *Journal of Chromatography* aided in the dissemination of discoveries. Other resources became available in the Chromatographic Science Series[7] and in compilations from the International Symposium,[8] which were drawn from the *Journal of Chromatography*. Column technology, which is central to a separation, was advanced with the development of numerous liquid phases and protocols to make possible interlaboratory comparisons of retention.

The fundamentals for separations with packed columns became organized and concise[9] at this time. In short, the essential methods for operating GC instruments, optimizing columns and controlling experimental parameters were developed during the 1960s, even though the technology was rudimentary. The refined technologies of the 1990s, when compared to developments in the 1960s, will be seen as improvements to previously described concepts and principles. Theoretical descriptions were provided with remarkable, though not complete, detail in this decade.

In the 1970s, three main themes arose in GC: the utility for GC methods in the burgeoning environmental and biomedical fields; the growing availability of comparatively inexpensive mass spectrometers as a detector in GC; and the commercial availability of capillary columns. In combination, these three influences radically transformed GC as a measurement science and pushed the method to the state of maturity that is seen today. Capillary columns were known to offer improved resolution over packed columns,[10] and capillary columns gradually supplanted packed columns throughout the 1980s. As a consequence, an entire line of investigation, namely, molecular interactions between substances and various stationary phases, and the efforts to create specialized stationary phases, was eliminated. In place of a vast number of stationary phases with specialized tools to evaluate and select an appropriate phase, only a small number of column types with superb resolution now meet most, if not all, analytical needs. Advances in optimization of chromatographic parameters[11] in terms of temperatures and flows made high resolution possible and sensible. Moreover, the optimization of column construction with respect to mixed stationary phases (packed columns) or lengths of columns in series (capillary columns) was made possible by the discovery of a linear relationship between partition coefficients and fractional composition.[12]

Throughout the 1990s, GC has experienced a period of enormous activity, although fundamental advances have remained relatively stagnant. Any basic advances, when made, occurred in incremental steps. In contrast, data acquisition became facile with inexpensive desktop computers, and comparatively inexpensive GC/MS became commonplace. Whereas in the previous generations, only large institutions could afford GC/MS instruments, the mass-selective detectors and ion traps of the 1990s placed GC/MS within the practical reach of even small laboratories.

3 PRINCIPLES OF GAS CHROMATOGRAPHY

The short summary given below can be supplemented by several extensive descriptions of chromatography, with special attention to GC.[13,14] In a GC experiment, a vapor sample is moved with a flowing gas (the mobile phase, generally either nitrogen or helium) through a glass or metal column containing a phase that is immobilized (the stationary phase). The stationary phase is typically a low-vapor-pressure liquid polymer, and is either coated or chemically bonded to a stationary support (either an inert solid or simply the inner wall surface of an open tube, i.e. a capillary column). As the mobile or gas phase is forced, under pressure, through the column, the sample components are also carried toward the detector at a speed dependent upon the chemical structure of the sample components, the characteristics of the stationary phase, the column temperature, and specifics of the column such as gas flow rate and the amount of stationary phase. Differences in the time of passage through the column (the elution time) are described by the extent to which a substance is dissolved into the stationary phase, i.e. the partition coefficient K which is equal to $[\text{analyte}]_S/[\text{analyte}]_M$, or the ratio of concentrations in the stationary and mobile phases. Thus, the separation process is founded in differences in the partition or solubility of various analytes in the stationary phase. It is the time spent in the stationary phase that prescribes the retention volume; all compounds spend the same amount of time in the mobile phase.

As the molecules are carried through the column by the carrier gas, an increased length of column should permit increased separation between different molecules with different solubilities. Unfortunately, other factors such as diffusion and resistance to mass transport cause broadening of the concentration profiles which lead to losses in resolution. Of all the terms that may be altered, resistance to mass transfer has offered the best opportunity for improvements and improvements have been attained with thin, evenly applied stationary phases; this is best exemplified with capillary columns. In general, control over diffusion is unwieldy in GC because the principal control is found in the selection of the carrier gas, where only two practical selections exist, nitrogen or helium.

Regardless of column design or stationary phase or sample, in GC the critical event is the partition of a substance between the gas phase and the stationary or liquid phase. The partition coefficient K is proportional to $(P^o)^{-1}$, where P^o is the vapor pressure of the pure substance. As vapor pressure is proportional to temperature, GC may be considered approximately as a type of distillation method and this general pattern can be seen in the separation of a homologous series of any chemical such as the *n*-alkanes. However, the subtle advantage of GC resides in the molecular interactions between the stationary phase and the sample, in which molecular interactions exert distinct influences on the solubility or partition

coefficient. This is expressed in the activity coefficient γ which contains both a thermal[15] (molecular interaction) and an athermal (size)[16] term. Thus, $K \propto (\gamma P^{o})^{-1}$ and resolution is controlled by more than vapor pressure alone; consequently, substances and even isomers within a chemical family can be separated by GC. In this respect, gas–liquid chromatography is complementary to gas–solid chromatography, in which separations occur through surface or adsorption interactions, which afford class separations through the large differences between functional groups or moieties.

A major theme in the development of the principles for GC separation was the creation of liquid phases that offer the best possible activity coefficients for a certain solute or sample. This was deemed necessary owing to the limited resolution of packed columns and led to the creation of a large number of stationary phases with tailored or specific intermolecular interactions. By the late 1970s, over 400 stationary phases were commercially available and confronted practitioners of GC with a problematic choice of the best stationary phase. As noted in the section below on **Column Technology in Gas Chromatography**, capillary columns afford resolution and separating capabilities that were impossible in previous generations with packed columns. Consequently, some inefficiency in separation could be tolerated if only an approximately good liquid phase was used, and so the number of stationary phases fell to under a dozen during the 1990s.

The discussion above suggests that GC is a fairly mature analytical method that has been well described for nearly two decades. Consequently, progress in fundamentals has slowed and the questions have become refined and focused. This pattern may be seen in biennial reviews which are made through the American Chemical Society in the section entitled "*Gas Chromatography*" in a special issue, entitled Fundamental Reviews, of *Analytical Chemistry*.[17–19]

4 OVERVIEW OF CONTRIBUTIONS

The discussions in the following articles amplify the themes given above and will reflect the current development of GC as a measurement technology. The reviews have been made broadly readable for those interested in GC, and are current for those who have an interest in recent advances in GC. The general utility of GC for substances that are vital to human health and environmental control is so widespread and effective that it is inconceivable that a dramatically improved technique will arise and suddenly replace GC methods. Certainly, there are no replacements plainly seen among other analytical methods, and GC should be a valued method so long as chemical determinations rely upon physical methods of characterization.

As noted above, one of the key revolutions in GC during the 1990s was the availability and consistency of bonded-phase capillary columns, and these columns have provided unprecedented consistency and resolution in GC methods. The foundations of these advances are described in **Column Technology in Gas Chromatography**. Another area where advances have occurred in the last decade and where future improvements may be anticipated is data processing. Chemical information can now be gleaned from chromatograms, using advanced methods of pattern recognition or using artificial intelligence to analyze GC findings. The most promising approaches are described along with the essential tools for interpreting chromatograms in **Data Reduction in Gas Chromatography**. As noted in the introduction, physical methods of chemical characterization were enhanced dramatically with a preseparation method such as GC, and these are described in **Hyphenated Gas Chromatography**. The performance and precision of GC measurements has been associated with the quality of instrumentation, and these are presented in the contribution entitled **Instrumentation of Gas Chromatography**. Although the number of liquid phases have been reduced in number, as described above, some knowledge of the chemical and physical properties of liquid phases is advantageous with GC measurements. The contribution entitled **Liquid Phases for Gas Chromatography** should provide the necessary background with an update on current trends. Perhaps one of the most exciting developments in GC is the addition of separating power through the use of two or more columns with different stationary phases during a single analysis. This approach has undergone a rediscovery for analytical measurements as described in **Multidimensional Gas Chromatography**. Although early developments in GC were invigorated through the capabilities to resolve and characterize complex mixtures of volatile organic compounds from natural products, useful information can be taken from a GC measurement only with high reliability for sample preparation. This is not trivial for complex, ultratrace or nonvolatile samples. Also, innovative methods of sample handling have extended the use of GC into previously difficult measurements with a wide range of substances. Consequently, any foundational evaluation of GC must include the methods for handling samples, and these are included in **Sample Preparation for Gas Chromatography**.

These categories include the core areas where GC continues to undergo changes or where recent changes have caused pivotal changes in the method. The sections, it is hoped, will provide a reference both for those who are unfamiliar with GC and for those who wish an evaluation

of the current standards and possible future trends in the method.

Column technology has fostered the development of gas chromatography (GC). As the manufacture of columns, especially capillary columns, has become more reproducible, the instruments have also improved. Chromatographic theory helps to guide the development of both the column and instrument in GC. Aspects of the theory directly related to the construction of columns are summarized. While packed columns can still be made in the local laboratory, the construction of capillary columns has moved to commercial vendors with the introduction of thin-walled fused-silica capillary columns. The technology required for the construction of columns is described.

1 INTRODUCTION

Over the last 40 years, GC has evolved into a widely used technique. Martin first proposed GC in 1951 and used packed columns in his investigations. Almost simultaneously with the commercialization of GC in 1957, Golay purposed capillary columns as a means of separation.[1] By the time of the 1961 conference on GC, Desty reported significant progress in applying capillary columns to petroleum-based samples.[2,3] The early investigators were practical and pragmatic, using materials readily available, such as metal tubing for capillary columns and industrial materials for supports.

The invention of fused silica in 1979 was the result of a systematic study of column materials for capillary columns.[4] At about the same time, a group in Stanford's Electrical Engineering Department reported on the design of a silicon micromachined gas chromatograph, where the gas sampling valve, column, and thermistor were fabricated on a silicon wafer.[5]

The invention of fused silica was significant in several ways. It provided a much improved inertness because of its low metal content, and it influenced stationary phase development because of the smoothness and wetting characteristics of the surface. The roughness of the packings in the packed columns and the metal capillary columns had allowed different phases to be used in column preparation and allowed the individual analyst to prepare columns for his or her own use. Investigators had to develop a better understanding of the interaction between the surface and the polymer used as the stationary phase in order to coat a wide range of stationary phases on to the fused silica. Fused silica also influenced instrument development because it became possible to manufacture very reproducible and stable columns. This article will focus on the manufacture of fused-silica columns and compare the design and manufacturing process with that of packed columns where appropriate.

2 THEORY AND OPERATING PRINCIPLES

The purpose of this article is to discuss GC column technology, not to go into great detail on GC theory. However, theory can be used as a guide for column selection and design, especially for capillary columns. Most commercially available capillary columns are described in terms of coating efficiency, retention index and capacity factor, k', in addition to their physical dimensions [length, internal diameter (ID) and film thickness, d_f]. Packed columns are described in terms of the support material, its size, and the amount of stationary phase, plus the column dimensions.

The purpose of the GC column is to provide the necessary separation for the compounds of interest. The capacity factor is a relative measure of how much a solute is retained and is defined in Equation (1) as

$$k' = t_r - t_m \quad (1)$$

where k' is the capacity factor, t_r is the retention time of the solute, and t_m is the retention time of an unretained peak (the minimum time required for a peak to pass through the column). The capacity factor is related to the partition coefficient (at a particular temperature) by

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

Equation (2):

$$K_D = \beta k' \tag{2}$$

where K_D is the partition coefficient of the solute at a given temperature and β is the phase ratio of the column, i.e. the ratio of the gas-phase volume to the liquid-phase volume.

Another parameter can be related to the retention time of the solute. The Kováts retention index gives a retention scale relative to a homologous series of compounds, usually the *n*-alkanes. The retention index for a particular isothermal temperature is given by Equation (3):

$$I = 100n\left\{\frac{\log(t_{rx} - t_m) - \log(t_{rN} - t_m)}{\log[t_{r(N+n)} - t_m] - \log(t_{rN} - t_m)}\right\} + 100N \tag{3}$$

where N is the number of methylene units in the least retained *n*-alkane and $(N + n)$ is the number of methylene units in the more retained *n*-alkane. Retention indices allow intercomparisons of columns in terms of their relative retention of different classes of compounds. For the siloxane phases, an aromatic compound such as acenaphthylene is used to show the relative differences in the stationary phase retention.

While the separation of components is primarily accomplished by the stationary phase selectivity in packed columns, capillary columns offer greater efficiency. This is considered in column selection along with the stationary phase selectivity. The column efficiency is experimentally determined by measuring the retention time, t_r, and the peak of interest's width at half-height, $w_{1/2}$. The efficiency can then be calculated using Equation (4):

$$n = 5.545\left(\frac{t_r}{w_{1/2}}\right)^2 \tag{4}$$

This gives the total plates for the column. For capillary columns, the column efficiency is normalized to column length, L, and is then given by Equation (5):

$$N = \frac{5.545(t_r/w_{1/2})^2}{L} \tag{5}$$

and is specified in plates per meter. An additional measure used with capillary columns is the concept of utilization of theoretical plates (%*UTE*) described by Equation (6):

$$\%UTE = \frac{N}{H_{min}} \times 100 \tag{6}$$

H_{min} is the theoretical minimum plate height and is derived from the Van Deemter equation, which is given in short form in Equation (7) as

$$H = A + \frac{B}{u} + Cu \tag{7}$$

where $A = 2\lambda d_p$, λ is a packing factor and is related to the particle shape and uniformity of packing, d_p is the particle diameter, $A = 0$ for capillary columns, $B = 2\gamma D_g/u$, γ is a correction term for the packing ($\gamma = 1$ for capillary columns), u is the linear velocity, D_g is the gas diffusion coefficient, and $C = 8(\pi k d_f^2 u)/[(1 + k')^2 D_L]$, where k' is the capacity factor, d_f is the film thickness and D_L is the diffusion coefficient of the solute in the stationary phase. As can be seen from Equation (7), the packed column efficiency is dependent upon the packing diameter, the uniformity of the packing material, and the uniformity of the packing process. The equation is simplified for the capillary column case. For capillary columns, the Golay equations are used.

Golay presented and subsequently published his seminal paper, "Theory of Chromatography in Open and Coated Tubular Columns with Round and Rectangular Cross-sections", at the International Gas Chromatography Symposium in 1957.[1] In his paper he derived the relationships for both circular and rectangular cross-section columns. For a circular cross-section column with radius r, the relationship is given as Equations (8) and (9):

$$du = \left(\frac{2D}{u_0} + \frac{1 + 6k + 11k^2}{24(1 + k)^2}\frac{u_0 r_0^2}{D}\right) dx_1 \tag{8}$$

$$\frac{du}{dx_1} = \frac{2D}{u_0} + \frac{1 + 6k + 11k^2}{24(1 + k)^2}\frac{u_0 r_0^2}{D} \tag{9}$$

These are now in the form of the Van Deemter equation, given as Equation (7). Note that there is no A term for the Golay equations. The A term deals with the support material in packed columns. For open-tubular columns, the equation is reduced to Equation (10):

$$H = \frac{B}{u} + Cu \tag{10}$$

The optimum velocity is derived by finding the minimum and is given in Equation (11):

$$\left(\frac{B}{C}\right)^{1/2} = u_{opt} \tag{11}$$

Solving the Golay equations for the minimum gives Equation (12) for the height equivalent theoretical plate H_{min}:

$$H_{min} = \frac{2r_0}{1 + k}\left(\frac{1 + 6k + 11k^2}{24}\right)^{1/2} \tag{12}$$

From these equations, we can see that for the circular cross-section columns the column diameter is a controlling factor for the column efficiency.

Two more concepts are important in the discussion of columns. The first is the concept of resolution, which is a measure of the ability to separate two different solutes, and the second is sample capacity (Equations 13 and 14):

$$R = \left(\frac{N^{1/2}}{4} \quad \frac{(\alpha - 1)}{\alpha} \quad \frac{k}{(1+k)}\right) \tag{13}$$

$$R = \text{column efficiency} \times \text{selectivity} \times \text{column capacity} \tag{14}$$

Column efficiency is primarily a function of the column diameter for capillary columns and particle diameter for packed columns. The selectivity is a function of the stationary phase and the third term is determined by the eluting compound's interaction between the stationary phase and the mobile phase.

Sample capacity also contributes to the resolving power. Sample capacity influences a column's capability for separation because if peaks are overloaded they will broaden and cause a loss of separation. Pretorius and Smuts[6] derived an equation for sample capacity (Equation 15):

$$M = \tfrac{1}{2}\sqrt{H_{\min} L}\pi r^2 (1+k) C_{\mathrm{M}}^{\ddagger} \tag{15}$$

where M is the weight of sample injected and distributed between the mobile and stationary phases and $C_{\mathrm{M}}^{\ddagger}$ is the maximum concentration of the component. The concentration of the solute in the stationary phase is dependent upon the nature of the solute and not the geometry of the column. Therefore, any difference in the weight of the sample in the stationary phase should be due to the stationary phase volume, which is dependent upon the geometry of the column. (This argument can also be extended to the mobile phase, where the volume determines the sample capacity.)

The best way to illustrate the effect of geometry on sample capacity is to consider two columns of equal length, coated with the same stationary phase, and with the same phase ratio and therefore the same capacity factor, k'. One column has an ID of 0.530 mm and the other column has an ID of 0.100 mm. Using the same stationary phase defines the maximum concentration in the stationary phase and is only dependent upon the choice of the stationary phase. Selecting columns with the same phase ratio also defines the value for the capacity factor and should be the same for the two columns. These assumptions allow the ratio of the expressions for the two different columns to be taken and is shown in Equation (16):

$$\frac{M_1}{M_2} = \frac{1/2\sqrt{H_{1\,\min} L}\,\pi r_1^2 (1+k_1) C_{\mathrm{M}}^{\ddagger}}{1/2\sqrt{H_{2\,\min} L}\,\pi r_2^2 (1+k_2) C_{\mathrm{M}}^{\ddagger}} \tag{16}$$

With $k_1 = k_2$ and the concentration maximum the same, Equation (16) reduces to Equation (17):

$$\frac{M_1}{M_2} = \frac{\sqrt{H_{1\,\min}}\, r_1^2}{\sqrt{H_{2\,\min}}\, r_2^2} \tag{17}$$

The ratio can be further reduced by substituting from Equation (12) that $H_{\min}$ is proportional to r. The ratio is reduced to the ratio of the column radius (shown in Equation 18) as an estimate of the effect of the column dimensions on sample capacity:

$$\frac{M_1}{M_2} = \frac{r_1^{5/2}}{r_2^{5/2}} \tag{18}$$

The comparison will become more complex as the lengths, phase ratios, and stationary phases are changed. Table 1 shows the relative sample capacity for different column diameters, but with the limiting assumptions made above. As can be seen from the comparison, as the diameter is decreased the sample capacity is considerably reduced. One development that has circumvented this limitation is to make multiple parallel capillary columns. The sample capacity directly increases as the number of columns increases. The sample capacity decreases at a faster rate than the column efficiency. There are many instances where the sample capacity can be the determining factor in the choice of a column.

The sample capacity of packed columns is higher. A 6 ft × 2 mm 5% methylsilicone Chromosorb® W 100–120-mesh packed column has about five times the sample capacity of the 30 m × 0.530 mm × 2.65 µm methylsilicone capillary column. The 6-ft packed column can only generate 3000–5000 total plates whereas the 30-m column can generate 60 000–75 000 total plates when operating near the optimum velocity. This capillary column provides nearly the same sample capacity but improved separation due to column efficiency and better column inertness.

Table 1 Comparison of relative sample capacity based on column diameter for columns of different column diameters with the column length and phase ratio the same for both columns

Column diameter (µm)	Sample capacity relative to 0.530-mm ID column
750	2.382
530	1.000
450	0.664

3 COLUMN CONSTRUCTION

3.1 Capillary Columns

The manufacture of capillary columns requires multiple steps. These steps will be briefly outlined to give an overview of the process before discussing the individual steps. To prepare a capillary column requires the choice of the column tubing material and the manufacture of the column tubing, a decision on pretreatments and deactivations, the choice of the stationary phase, the choice of the coating technique and coating solvent, if the stationary phase is to be cross-linked then the choice of the cross-linking initiator, if the column is to be rinsed then the rinse solvent, and the conditioning prior to use.[7]

A variety of tubing materials have been used for the construction of capillary columns. Initially, commercially available metal tubing was used. This had some inherent advantages for the early investigators in that the surface roughness allowed different stationary phases to be tried and used. The major limitation was the activity of the tubing. This motivated investigators to develop the means for drawing glass capillary tubing. Much of the work used either soda-lime glass (called this because of the Na_2O in the glass) or a borosilicate type of glass. The presence of the Na_2O lowers the melting temperature of the soda-lime glass, which makes it easy to work with. Similarly, borosilicate glass (which has B_2O_3 as a flux in the glass) has a lower melting point than SiO_2 (see Table 2 for glass composition). Silicon dioxide glass is available as either quartz or fused silica. Quartz is a naturally occurring material obtained through mining and can contain trace metal contaminants, sometimes at significant enough levels to affect the chromatographic performance of the column. Fused silica is a synthetic material prepared by oxidizing tetrachlorosilane to silicon dioxide. This process leads to a very pure material, with very low metal content and a low concentration of chloride. Soda-lime and Pyrex glasses were drawn using a relatively small machine (roughly 20 in by 30 in) that would automatically coil the drawn capillary. This tubing was thick walled and required the ends of the tubing to be straightened. While column end straighteners were made to help with this task, the inexperienced chromatographer still found that this required straightening before installation into the gas chromatograph was difficult to master. This caused reluctance to use capillary columns. Up until the invention of the thin-walled fused-silica capillary columns, the manufacture of capillary columns was still the domain of chromatographers in private laboratories and with limited commercialization. Inexpensive drawing machines and devices for straightening the column ends were available to these laboratories.

The purity of the fused-silica material is important because it allows the tubing to be drawn as thin-walled tubing. The primary benefit of the thin-walled tubing is that it is inherently straight. For smaller diameter columns the outside diameter (OD)/ID ratio is increased to stiffen the material. If these columns were drawn with the same OD/ID ratio as the larger diameter columns, such as the 530-mm columns, the tubing would be limp and harder to handle. Thus it is more difficult to maintain the integrity of the sealing surface by requiring smaller diameter ferrules or excessively extruding graphite ferrule material. It is also harder to make the ferrules with the smaller OD columns. Although it is possible to draw other glasses into thin-walled tubing, it is not practical. The presence of the fluxes (Na_2O, CaO, etc.) in these glasses considerably reduces the inherent strength of the silicon dioxide. Another mechanism, sodium devitrification, also affects the strength of the silicon dioxide. The presence of sodium eventually causes the glass to form microcracks. With the thicker walled tubing this not a problem, but the thin-walled fused-silica tubing requires a protective sheath. The protective sheath is necessary because sodium is picked up very easily during the handling of the column. The protective sheath is normally polyimide with a temperature limit in the 350–375 °C range. The temperature limit will be determined by exactly which polyimide is used (above this temperature the polyimide begins to oxidize). The polyimide used at the introduction of fused-silica columns in 1979 could be completely removed by exposure to 400 °C for 1 week. Aluminum has also been used as a sheath material to extend the time of exposure to high temperatures (400–450 °C). When coating the protective sheath on to the thin-walled fused-silica tubing, care must be taken not to trap particles between the polyimide and the fused-silica tubing. Particles can be a source of abrasion and sodium, both of which can cause microcracks and eventually breakage of the column. Therefore, the drawing process now requires a very clean environment and a much larger area. The drawing machine has now become a clean room with enough room for the drawing tower (this requires a ceiling

Table 2 Composition of different glasses (%)

Glass type	SiO_2	Al_2O_3	Na_2O	CaO	MgO	B_2O_3	BaO
Soda-lime	68	3	15	6	4	2	2

Figure 1 Schematic diagram of a fused-silica capillary column drawing tower.

height of 20–30 ft or higher). The laminar flow for the air greatly reduces the number of particles on the tubing prior to application of the protective sheath. The drawing tower (as shown in Figure 1) consists of the framework for the mounting of the different equipment, the feed mechanism for the preform (typically 1 m or greater in length), the graphite furnace where the preform is drawn down to the required OD and ID, the polyimide applicator, and a length of drying ovens to cure the polyimide before the tubing reaches the take-up reel. If the polyimide is not cured, the drawn tubing will bond together. The cost of preparing the thin-walled fused-silica tubing in private laboratories is essentially prohibitive and fused-silica tubing is therefore commercially prepared almost completely. The preparation of the columns has also shifted to the column vendors.

As the column preparation continues, the next steps will prepare the tubing to be coated with the stationary phase. After the tubing has been drawn, the desired length is cut and, for the fused-silica tubing mounted on a basket, the column can be pretreated. For the softer glasses, several pretreatments were used, including leaching with dry hydrogen chloride gas and growing barium carbonate crystals on the surface. These techniques were carried out to improve the wettability of the surface by increasing the roughness of the surface. The fused-silica material is not as easily leached, for several reasons. The thickness of the residual water layer is less than that of the softer glasses, and for the softer glasses the presence of the leachable metals allow the leaching to go deeper and to occur more quickly. These metals on the atomic scale have large hydrodynamic radii, which helps the leaching of the glass. In fused silica these metals are absent. While the pretreatment methods tend to be gas-phase-based for the softer glasses, pretreatment methods for fused silica tend to be liquid-based. For the fused silica, this first step may be as simple as a rinse with distilled water or other dilute aqueous solutions. This pretreatment can be used to increase the number of surface silanol groups. Silane, siloxane, and silazane regeants can then be reacted with these groups to complete the pretreatment or deactivation.

Deactivation can also be done prior to the coating of the columns. Carbowax 20M™ is a polyethylene glycol that can be used both as a stationary phase and a deactivation agent. When it is used for deactivation, a plug of Carbowax™ solution is passed through the column, the column is sealed and then heated to 280 °C for a period of time (this can be as long as overnight). At the completion of the deactivation time, the column is cooled and unsealed. It is then rinsed with a rinsing solvent to remove the residue and then purged to remove the residual solvent. Other types of deactivation include siloxane-based deactivations. One of the earlier of these deactivations is the D_4 deactivation, where D_4 represents cyclic octamethyltetrasiloxane. The plug of D_4 is passed through the column and the column ends are sealed. The column is then heated to 400 °C. At 400 °C, the cyclic siloxane slowly opens and will react with both the fused-silica surface at the surface silanols and with itself to produce a thin deactivated layer on the interior surface of the column. Other deactivations are based on more reactive reagents, such as the disilazanes, and react under milder conditions. Still other proprietary compounds and techniques are used by the column manufacturers.

The next step is the coating of the column with the stationary phase. The coating step can be carried out on untreated material, but many of the stationary phases require pretreatment and/or deactivation steps for efficient columns to be prepared. To illustrate how deactivation affects this process, the coating of a phenylmethylsiloxane of molecular weight 3000 was carried out on Carbowax™-deactivated, D_4-deactivated and undeactivated fused-silica columns. The only column of these three that was an efficient (i.e. well coated) column

was the column with the Carbowax™ deactivation. The phase will bead up on the other two columns. This low-molecular-weight stationary phase is a liquid. To coat the fused silica properly required a higher molecular weight phenylmethylsiloxane (a gum rather than a liquid) to be developed. While these gum phases were readily available for polydimethylsiloxane and 5% phenylmethylsiloxane copolymer at the introduction of fused-silica columns, the other phases were not. Much of the research into capillary columns during the 1980s was devoted to optimizing stationary phase development. Much progress was made in the development of stationary phases with higher molecular weight, hence with better wetting of the column surface. The better wetting of the surface is necessary for the production of efficient columns. These phases now include phenylmethylsiloxane (also denoted 50% phenylmethylsiloxane) and cyanopropylmethylsiloxane, which extend the polarity of columns available to the chromatographer. Simply increasing the molecular weight does not necessarily produce a viable phase. For example, to coat the phenylmethylsiloxane column efficiently on material that has not been deactivated requires a gum phase of molecular weight ~100 000. Grassie et al. reported that with polymers built with the phenylmethyl monomer, the longer the polymer chain length, the more it will react with itself.[8] This manifests itself with a choppy baseline as the column is temperature programmed to 300 °C. Either the polymer chain must be interrupted or a different starting material for the polymer must be used. If diphenyldimethylsiloxane is used as the chain repeating unit, this problem may be avoided.

The gum phases used with fused-silica columns have affected the production of the columns in a different way. With the higher molecular weight stationary phases, the coating solution becomes very viscous as the concentration of the stationary phase increases. This limits the technique of coating the column to primarily the static coating technique. For lower molecular weight phases, the dynamic coating technique can also be used. The dynamic technique will be discussed first. To carry out dynamic coating requires the preparation of a concentrated stationary phase solution (usually in the 10–20% range). A volume of 2–4 mL of this solution is transferred to a coating station consisting of a fitting that includes a connection to an inert purge gas source and a reservoir for the coating solution. A plug of solution is then introduced into the column and pushed along by the gas. The speed at which this plug moves determines the film thickness. This technique will work better with the wider bore capillary columns, such as 530-μm ID columns, because the pressure drop is not as great and therefore the film thickness will not change as much. With longer, smaller diameter columns such as 200-μm ID columns, the film thickness will vary more because the pressure drop is higher. This causes the velocity to increase rapidly as the plug nears the exit of the column. The column to column repeatability is not as good as with the static coating technique.

The static coating technique is carried out by filling the column with the coating solution. Once the column has been filled, the exit end of the column is sealed. The column is then attached to a vacuum source and the solvent is slowly evaporated, leaving the stationary phase behind. Once the column has been evacuated, further reaction and conditioning of the stationary phase can occur in the column. The concentration of the stationary phase can be calculated using Equation (19):

$$\beta = \frac{\text{volume mobile phase}}{\text{volume stationary phase}} = \frac{V_m}{V_s} = \frac{\text{volume of the volumetric flask}}{\text{density} \times \text{weight of the stationary phase}} \quad (19)$$

The density for the polydimethylsiloxane phases is 1.0 g mL^{-1} and the solution phase ratio is easily calculated. For other stationary phases it is necessary to include the density to calculate the film thickness of the stationary phase properly. Thus, to prepare a coating solution of dimethylpolydimethylsiloxane for a phase ratio of 250 would require dissolving 1.000 g of the phase in a 250-mL volumetric flask. Once the phase has dissolved in the solvent, the solution can be used for coating columns.

As seen from the brief description of the static coating process, the choice of the solvent for the stationary phase is important and helps to determine the length of time required to coat the column and the range of film thickness that can be coated with the solvent–stationary phase combination. Solvents with high volatility (low boiling points) such as pentane (36.05 °C), methylene chloride (39.85 °C), and acetone (56.1 °C) have been used for static coating of columns. The polydimethylsiloxane phases are readily soluble in pentane. Whereas the low-molecular weight polyphenylmethylsiloxanes (liquid) are appreciably soluble in pentane, the higher molecular weight gums of the phenylmethylsiloxanes are not and require a different solvent, such as methylene chloride. Since the column length can be between 10 and 150 m, the filled column is a very effective thermometer which responds to small changes in the temperature of the environment around the column while the column is being evacuated. During the evacuation process, the column must be shielded from the temperature swings in the room and, if coating baths are used, from the temperature swings of the heaters. The high-volatility solvents tend to have the higher coefficients of thermal expansion. As the coating solution expands or contracts it will wash the already deposited phase and change the coverage of the column. To a lesser extent, the concentration of the solution changes and will deposit less at higher temperatures or more at lower

temperatures. Sudden cooling of the solution will cause the coating solution to contract and can leave uncoated areas along the column. The thicker the coating solution, the less prone it is to this behavior. If the coating solution is not degassed it may cause cavitation problems when pumped with a high-pressure liquid chromatograph pump. The trapped gas can also cause problems with the evacuation process by expanding and pushing the coating solution along as it expands. This will happen when the pressure drop is high enough to cause the bubble to expand. When this occurs, the whole or part of the column can be washed out. Again, thicker stationary phase solutions tend to reduce this tendency.

The static coating technique requires a high-pressure pump, such as a liquid chromatograph pump, for the higher viscosity solutions to be filled. The columns must then be sealed without trapping air at the end. A vacuum system must be available to evacuate the columns and a means (such as a buffer volume) must be provided to bring up the vacuum slowly. Care must be taken to hold the temperature as constant as possible. Quick temperature swings around the columns should be avoided.

After the columns have been evacuated, the next step in the process is the cross-linking step.[9] The cross-linking agent must have several characteristics to be a good choice for the column-making process:

1. It must dissolve in the coating solution at the required concentration.
2. It cannot be volatile at the column evacuation temperature.
3. It must react at a temperature less than the maximum recommended operating temperature for the phase and preferentially at the lowest temperature as possible (this allows the stationary phase to remain as viscous as possible).
4. It should not degrade or change the stationary phase characteristics. Usually, this is accomplished by the cross-linking occurring at vinyl end caps, methyl groups, or OH groups remaining in the stationary phase or on the fused silica. Cross-linking via the methyl groups on a dimethylpolysiloxane would proceed as follows:

   (a) Free radical formation:

   $$R{-}R \longrightarrow 2R^{*}$$

   (b) Abstraction of hydrogen:

   $$R^{*} + CH_3(SiO)CH_3 \longrightarrow RH + {}^{*}CH_2(SiO)\,CH_3$$

   (c) CH_3 recombination of radicals to cross-link dimethylpolysiloxane:

   $$2{}^{*}CH_2(SiO)\,CH_3 \longrightarrow CH_3(SiO)CH_2{-}CH_2(SiO)$$

5. The decomposition products should be easily removed with purging and/or solvent rinsing.

The cross-linking is carried out by dissolving an initiator such as dicumyl peroxide **(1)** in the stationary phase solution. Once the solvent has been evaporated, the column contains the stationary phase and the initiator. The column is then slowly purged with an inert gas as the temperature is increased. Dicumyl peroxide decomposes to the peroxide radical for the cross-linking reaction to occur. After the cross-linking step is completed, the column is usually rinsed and then carefully conditioned under flow. The choice of solvent and thermal conditioning profile will be determined by the stationary phase.

(1)

The final step in the process is to test the column. Several different parameters are checked using chromatographically well behaved compounds such as the *n*-alkanes on the siloxane-based stationary phases:

- the capacity factor, k'
- the retention index, *RI*
- the coating efficiency.

Other compounds are typically chosen to show the inertness level of the column (using acidic and basic compounds) and the resolving power of the column with closely eluting pairs of compounds, such as the xylenes. Application-specific columns are tested with representative compounds for the application.

3.2 Packed Columns

The manufacture of packed columns requires fewer steps than capillary columns. These steps will be briefly outlined to give an overview of the process before discussing the individual steps. To prepare a packed column requires the choice of the column tubing material, the choice of the support material, a decision on pretreatments and deactivations of the support material, the choice of the stationary phase, the choice of the coating solvent, and the packing technique.[10–13]

Several different materials have been used for the tubing material for packed columns, including metal tubing, glass tubing, and polymeric tubing. The choice of tubing will depend upon how the packed column will be used. Glass or glass-lined tubing is used when activity levels need to be reduced. If glass tubing is used, it must be preconfigured to fit the gas chromatograph in which it will be used. The metal and polymeric tubing are also coiled, if necessary. The nature of the packing material may require that the coiling of the metal tubing be done prior to loading of the packing.

The support material is typically a porous material, although glass beads have been used. The materials used for the support include diatomaceous earth, zeolites, porous polymers, and carbon-based material, such as charcoal. For the diatomaceous earth supports, the source of the diatomaceous earth, the treatments, whether acid washed and treated further, and any deactivation steps contribute to the inertness of the column along with the column tubing.

Once the appropriate support material has been selected, the stationary phase is applied to the support by dissolving the phase in an appropriate solvent. Since packed column loadings typically range from 1 to 20% (w/w), the phases tend to have lower molecular weights than comparable phases used with capillary columns. This is because of the limited solubilities of the higher molecular weight gums used for the manufacture of the capillary columns. The stationary phase solution is usually prepared with a higher boiling solvent than would be used with the capillary columns. The stationary phase solution is added to the packing and mechanically mixed, usually by rotating, and the solvent is evaporated.

When the solvent has been removed, the coated support material is then loaded into the tubing using a funnel to direct the material into the tubing and is mechanically agitated, usually by tapping to disperse the material throughout the length of the column. Plugs are placed at the ends of the columns to hold the material in place.

Comparison of the range of stationary phase loading for packed columns with the phase ratios of capillary columns requires the phase ratio of the packed column to be estimated. The phase ratio of a 6 ft $\times$ 2 mm 5% polymethylsiloxane on Chromosorb W®, 110–120 mesh, is estimated to be about 58. The 1–20% range of column loading corresponds to a phase ratio range of 15–300, while the phase ratio range for capillary columns is typically 25–500. To increase the column efficiency, the particle diameter must be reduced, which increases the pressure drop across the column. As with capillary columns, there is a trade-off with increased column efficiency and increased pressure required.

4 PRESENT AND FUTURE DIRECTIONS IN COLUMN TECHNOLOGY

Although fused silica has provided a very stable and inert support, there are applications, such as high-temperature simulated distillation, which will rapidly degrade a methylsiloxane column, both on the inside and outside of the column if the column is polyimide coated. The polyimide has a threshold of $\sim$350 °C for its oxidation. Continuous exposure at 400 °C for a period of about 1 week will strip the column of its protective coating. The methylsiloxane column will also show significant reduction in its ability to partition the solute. These losses have led to other approaches, such as depositing a layer of silica on the interior of the metal capillary tubing and the development of arylene-based stationary phases. The arylene-based stationary phases have arylene units introduced into the polymer backbone.

There has also been a movement towards miniaturization in analytical techniques and instrumentation. Over the past 20 years, researchers have investigated the use of silicon-based materials for capillary columns. This requires the application of microlithographic techniques to column manufacture. One desirable feature of this approach is the fact that the silicon material presents a thin silica layer. This layer is known as the native oxide layer. In the processing of silicon wafers, there are several different methods of growing or depositing an oxide layer on the wafer. The thermal oxidation of the silicon grows the highest density oxide layer. This thermal oxide is much like the drawn fused silica in its density. A second technique for depositing the oxide is chemical vapor deposition (CVD), which can give a more porous silicon dioxide layer. The inherent problem with columns developed using microlithographic techniques is that microlithography is essentially carried out in two-dimensional (planar) space. The channels for the columns are prepared by using controlled etch solutions. The final step in preparing the columns is to seal a second plate over the etched channel and make connections to the plate. Coating these plate columns with stationary phase presents a different set of problems. This approach will require these problems to be solved in order for it to be viable.

Molecular sieves represent another area where some interesting work is being done. UOP mat/sen (El Dorado Hills, CA) has developed several different molecular sieves that are very specific for different gases. While these specialty molecular sieves have applications as traps, there may also be ways to utilize these materials for porous layer open-tubular (PLOT) columns and micropacked columns.

As can be seen, column technology has utilized a wide range of materials and techniques. Further advances will be made through the systematic application of materials

science, polymer chemistry, and a variety of analytical techniques.

LIST OF SYMBOLS

α	selectivity
β	phase ratio of the column, i.e. the ratio of the gas-phase volume to the liquid-phase volume
γ	correction term for the packing
λ	packing factor related to the particle shape and uniformity of packing
$C_M^{\ddagger}$	maximum concentration of the component
d_f	film thickness
d_p	particle diameter
D_g	gas diffusion coefficient
D_L	diffusion coefficient of the solute in the stationary phase
H_{min}	theoretical minimum plate height
k'	capacity factor
K_D	partition coefficient of the solute at a given temperature
L	column length
M	weight of sample injected and distributed between the mobile and stationary phases
n	column efficiency
N	column efficiency normalized to column length, usually plates per meter
R	resolution
t_m	retention time of an unretained peak
t_r	retention time of the solute
u	carrier gas linear velocity
$\%UTE$	utilization of theoretical plates
$w_{1/2}$	width at half-height

ABBREVIATIONS AND ACRONYMS

CVD	Chemical Vapor Deposition
GC	Gas Chromatography
ID	Internal Diameter
OD	Outside Diameter
PLOT	Porous Layer Open-tubular

The data obtained from a gas chromatographic measurement provide the user with details on both the quantitative and the qualitative composition of the sample. This information is displayed in the chromatogram from which information also can be gleaned concerning the performance and quality of the measurement. Quantitative determinations require attention to the relative response of the detector. The assignment of identity of individual constituents is possible in a formal sense only with authentic standards and mass spectra though retention times or indices can be indicators of identity. These aspects of data reduction have been understood for several decades and chemical information can be extracted from a chromatogram with ease and convenience.

In recent years, advanced chemometrics methods have been applied to chromatographic data with intrinsic advantages for probing patterns and trends too subtle or too complex for simple inspection of chromatograms. These methods are rooted in tools such as multivariate analysis and neural network analysis. Such methods are being developed in the area of natural products analysis.

1 INTRODUCTION

A chromatogram is the immediate result obtained from any analytical measurement by gas chromatography (GC) and discloses, for most detectors, all the chemical information about a sample that will be provided by the GC experiment. In addition, details about the overall performance of the chromatograph can be found in the chromatogram and diagnostics are best made when a known sample such as a standard mixture is analyzed. A chromatogram is a plot of detector response (usually in current or voltage) versus time (usually in minutes) following the introduction of a sample into the chromatograph. Most analyses by GC conclude with an understanding of the concentrations or amounts of one or more constituents in a sample and some indication of the chemical identity of such constituents. These results are readily available from the chromatogram and this accounts for the wide acceptance of GC as an analytical tool. At an elementary level, the information and the methods to extract this information have been unchanged during the last several decades and can be found in specific monographs on GC[1,2] or in general analytical chemistry texts.[3,4] These will be reviewed and illustrated concisely in the next section.

In addition to the routine use of chromatographic data to answer questions such as 'is there benzene in my sample and if so how much is there?', there may be interest in using the chromatogram for comparing with results from other samples. This might be motivated by interests in the origins of the sample or to learn if subtle changes in sample composition had occurred during storage, treatment, or processing of the sample. Normally, human skills of comparison are eclipsed when samples are highly complex or numerous. For example, observing the differences or similarities between chromatograms containing more than 20 peaks can be daunting especially when there may be only minor differences in concentrations of several components. Small differences in chromatograms from GC analysis of volatile organic compounds in blood or urine or breath might be essential in determining an illness, but easily overlooked without computation aids.

While comparisons of complex chromatograms are impractical through manual methods of data reduction, advanced computational methods can provide the necessary tools for such comparisons. These methods have been refined rapidly during the last few years with the wide

availability of affordable, powerful and small computers and the release of specialized, commercial software for advanced data reduction. In the third section below, two of the promising methods for advanced data reduction are described.

2 ESSENTIALS OF CHROMATOGRAPHIC DATA

2.1 General Facets of a Chromatogram

In Figure 1, a gas chromatogram is shown from the analysis of a standard mixture of normal alkanes by gas chromatography/mass spectrometry (GC/MS) and the results are useful for illustrating the information that can be gleaned from an analysis by GC. The important terms for the analyst include the number of constituents (seen ideally as separated or well-resolved peaks) and the relative abundances of each constituent (i.e. the relative heights or areas of each peak, as a rough approximation). Each peak can be defined by a few terms including: the retention time (t_r), peak area (or height), peak width (w), peak shape distortion or asymmetry factor (η), and the retention time for an unretained compound (t_m). These all assist in expressing the ultimate goal of a chromatographic experiment, namely, the satisfactory separation or resolution of constituents in a mixture. Other terms such as column length, carrier gas flow rate, inlet pressure, ambient pressure, and column temperature cannot be obtained from the chromatogram and are acquired from independent measurements. Such terms are especially useful when studying the details of chromatographic behavior but are not essential for analytical purposes. All these terms and their meaning have been standardized over the last 30 years[1–4] and are helpful in determining or documenting the composition of the sample or in exploring separation processes.

Figure 1 Gas chromatogram of *n*-alkanes taken with temperature programmed analysis. The analysis was made using a capillary column in a gas chromatograph mass spectrometer. Thus, the solvent peak was eluted and vented before data acquisition by the mass spectrometer was started. The chromatogram shows the general appearance of well-resolved peaks in a mixture.

The retention time is the timescale of the chromatographic measurement as shown in the *x*-axis of the chromatogram in Figure 1 and is measured from the point of injection (not seen in the figure). Each peak is assigned a retention time measured at the peak maximum for a substance and this is shown in Table 1. For example, the first peak has a retention time (t_r) of 8.154 min and the second peak shown has a t_r of 13.084 min and these supply information regarding the chemical identity of that peak as described below. In addition, the peak heights or areas contain information about the amounts of substances in the sample and this too is described below. A salient feature of the chromatogram before detailed discussion is the information so often sought: this sample shows the presence of six constituents and the amounts of each, as a first approximation, appear comparable in order of magnitude.

2.2 Quantitative Aspects of Gas Chromatography Data

The size of any peak is a measure of the amount of that chemical in the sample and there is a proportional relationship between peak area (or peak height) and amount of chemical (number of molecules, moles, mass, or concentration). However, all detectors in GC are operated on principles where there is some discrimination, based upon molecular structure, in the sensitivity of response (Δ response/Δ amount). Consequently, any direct comparison of peak heights of various substances without consideration of differences in detector response will be erroneous. Quantitative determinations for GC will be accurate only when the amount or concentration of each analyte is determined using individual calibration curves made for that specific analyte or when relative response factors can be used to normalize a response. Highly selective detectors such as electron capture detector (ECD)

Table 1 Results from analysis of chromatogram in Figure 1

Peak number (see Figure 1)	Retention time (min)	Width (min)	Area	Start time (min)	End time (min)
1	8.154	0.156	330 211 451	7.841	8.912
2	13.084	0.140	555 572 742	12.523	13.453
3	19.125	0.131	444 008 379	18.702	19.485
4	25.666	0.132	576 691 495	25.229	26.189
5	32.272	0.161	990 352 553	31.727	33.174
6	38.637	0.180	1 152 937 448	37.906	39.546

Table 2 Differences in response for various chemicals in two GC detectors. Absorption coefficients and normalization factors are measures of relative response for the same amount of chemical used in the original literature. Exact definitions can be found in refs. 5 and 6

ECD			
Chemical	Absorption coefficient	Chemical	Absorption coefficient
Methylene chloride	1	Chlorobenzene	1
1,3,5-Trichlorobenzene	60	*o*-Dichlorobenzene	42
Chloroform	500	*p*-Dichlorobenzene	11
Hexachlorobenzene	1100	Vinylchloride	0.1
FID			
Chemical	Normalization factor	Chemical	Normalization factor
n-Hexane	1.00	1-Butanol	0.66
Cyclopentane	0.98	Acetic acid	0.24
Benzene	0.97	Ethylacetate	0.38
2,2,4-Trimethylpentane	0.98	Acetone	0.49
1-Methyl-3-ethylbenzene	1.03	Ethyl phenyl ketone	0.80

FID, flame ionization detector.

and nitrogen-phosphorus detectors exhibit differences in response factors by orders of magnitude as shown in Table 2.[5] Other detectors such as the FID show a small range of responses within a chemical group such as alkanes though response factors may differ widely between chemical families.[6] In practice, this means that calibration curves should be made for each chemical. Creating individual calibration curves is not burdensome in GC methods since the separation capabilities allow standard solutions to be made as mixtures and calibrations to be made simultaneously for many constituents with a few analyses. The results in Figure 1 were taken from a mass spectrometer detector and the peaks are all alkanes with comparable response factors. Not all peaks have same intensity or height (or area), so differing concentrations between the constituents may be reasonably concluded (Table 1).

If chromatographic performance between samples and standards is identical or very similar, peak heights are suitable for quantitative work or peak areas may be used and are especially helpful when slight variations exist in chromatographic performance. These terms are generated automatically with modern gas chromatographs which are manufactured with data analysis options of varying degrees of sophistication. Difficulties arise in the automated determination of areas for partially resolved components. In the instance when best chromatographic performance is obtained and peaks are still not totally resolved, deconvolution of the chromatogram may be helpful. At present, commercial software packages allow deconvolution of peaks as shown in Figure 2 and these afford refined methods for obtaining peak areas.[7] The additional time and expense in data reduction for these deconvolutions is returned in analytical information that may not be obtainable otherwise.

2.3 Qualitative Aspects of Gas Chromatography Data

A second aspect of data reduction is the determination of the chemical identity for a peak and there is no true substitute for a mass spectrum of a peak as shown in Figure 1. The combination of prefractionation by GC with chemical identification by mass spectrometry (MS) explains, in part, the explosive growth of GC/MS instruments and methodologies. This principle about chemical identity cannot be diminished and is especially critical for samples where there is little or no understanding of possible constituents. In some instances where the number of constituents is limited and the sample is drawn from a well-characterized and fairly stable source, retention time of a peak (t_r) is a de facto measure of chemical identity. In these instances, this measure will suffice as all the proof necessary for an assignment of identity. In other instances, nothing short of a mass spectrum for a peak in a chromatogram and a confirmation of the analyte retention time with an authentic sample will be satisfactory for identifying a constituent in a chromatogram. Regardless, the retention time (t_r) is and has been an essential term in GC analyses and is best reported as the corrected retention time t'_r where the time is corrected and normalized to the time for an unretained solute (t_m) as shown in Equation (1). While selection of an unretained solute is more difficult than may be expected, methane is commonly used when column temperatures are high and the detector is a FID (hence the term t_m). In mass spectrometers, where

Figure 2 The use of deconvolution in obtaining peak areas for a chromatogram (a) in which there is incomplete chromatographic resolution. (b) The individual peaks as seen from deconvolution are shown. The results were generated using PeakFit 4.0.

the filament is usually started after the solvent or air peak has eluted, a reliable determination of t_m is inconvenient and must be made in a separate determination.

$$t'_r = t_r - t_m \tag{1}$$

The great facility of a corrected retention time is that there is a direct reference to the partition coefficient (K) of the analyte via the phase ratio for the column (β) as shown also in Equation (2). The value K is dependent upon stationary phase,

$$\frac{t'_r}{t_m} = \frac{K}{\beta} \tag{2}$$

chemical compound, and temperature. So, if stationary phase and temperature are controlled, K (and thus t'_r) will be characteristic for a given chemical.

Unfortunately, phase ratios are difficult to obtain or modify so practical chemical measurements require a means to compare results between laboratories. One means used in recent decades to allow comparison of chromatographic results on a given stationary phase is the use of chemical standards to calibrate retention times. A common standard comprised a homologous series of normal hydrocarbons and was called the Kovats index.[8,9] In this method, the retention of a chemical was expressed in carbon numbers, rather then retention time, by referencing retention for constituents to the retention of a set of *n*-alkane standards. Any differences in physical parameters of a column (flow, length, temperature, and phase ratio) would be compensated by this calibration of retention to chemical standards. Such methods were particularly useful since many chromatographers used self-made columns where experimental variables ranged widely. With the advent of commercial capillary columns manufactured with stringent quality control, retention times are matched via software to stored library values

and adjustments using carrier gas flows are made to meet standard t_r values. In this way, retention times are directly intercomparable between instruments or laboratory using retention timescales though retention on a column, in a sense, is still being calibrated against a chemical standard.

2.4 The Chromatogram as Diagnostic Tool

A final aspect of the chromatogram is that which provides a full measure of the performance of the gas chromatograph including injection port, column, and detector. A full discussion can be seen in sections on trouble shooting[1] and a brief discussion is given here.

Peaks that exhibit tailing are usually an indication of adsorptive interactions between the sample and surfaces in the inlet, column, or detector, poor flow connections, or overloading of the stationary phase. Active sites, that is highly polar or reactant surfaces in the inlet, column, or detector, are usually remedied through chemical deactivation of these sites. Alternatively, improved materials or new columns or improved designs may be needed.

Peaks that show front skewing are indicative of excessive sample loading on the column and the partition coefficient has been pushed into a region where the isotherm of C_l versus C_g is nonlinear where C_l and C_g are the concentrations of the sample in the liquid and gas phases respectively. This is shown in Figure 3.

When a hydrocarbon sample shows tailing on a fresh, nonpolar or semipolar column, the responsibility is usually poor connections or fitting and is shown in Figure 3. Drifting baselines and more are treated in a recent monograph that experimentalists will find useful.[1]

Band-broadening is a normal part of a chromatogram[10–12] and many of the advances in high resolution chromatography have occurred through improved management of band-broadening.[13] Additional band-broadening can arise through the injection of sample and other extra column contributions. These and baseline changes are treated in a series of practical guides.[14–16]

Figure 3 Two examples of peak distortion. (a) shows overloading of the liquid phase and (b) shows tailing indicative of a poor connection. The asymmetry factor is a ratio of distances from a center line.

3 ADVANCED DATA REDUCTION METHODS IN GAS CHROMATOGRAPHY

When chromatograms are simple and information regarding a single (or a few substances) is sought for a measurement, interpretation of the chromatogram can be uncomplicated and rapid. However, when chromatograms contain large numbers of peaks and the patterns defy simple interpretation, advanced methods of data reduction can be useful. There have been two approaches, broadly speaking, to coping with complex samples and these include principal component analysis or cluster analysis and neural network methods. Both methods are computationally intensive and have blossomed with the rise of personal computers in the 1980s and 1990s.

3.1 Multivariate Data Analysis in Gas Chromatography

In multivariate data analysis, data are manipulated so that subtle relationships between constituents in the data can be resolved or clarified. This is done by mathematical methods of recreating the reference points in the information contained in the data and the details of these methods can be found in the articles referenced below. The goal in multivariate analysis is to amplify similarities or differences in data for various samples and generally minimize the number of variables that

Figure 4 Principal components plot for fatty acid content of vegetable oils in 2-D (a) and 3-D (b) plots. (Drawn from the article by Lee et al.,[17] used with permission.)

describe a sample. The tools and rules to identify or create the terms for comparisons (principal components in principal component analysis) are beyond the scope of this article. It is sufficient to say that certain peaks or regions of a chromatogram may be compared with other peaks as a measure of similarities. When done for several such comparisons, computational methods allow rapid analysis of results. The end goal is the assignment of a sample as a single data point in two-dimensional (2-D) or three-dimensional (3-D) plots or in multidimensional space. The presence of other measurements in proximity to the sample constitutes evidence of a common or unique composition or identity.

An example of one use of these tools is principal component analysis of chromatographic data from characterizing fatty acids in vegetable oils.[17] Though the chromatograms were comparatively simple consisting of only ~10 fatty acids, the number of sample types were numerous including olive, coconut, sesame, and others. The results are shown in Figure 4 where the various types of samples are resolved in 2-D and 3-D.

Another example of a chemometric approach to processing gas chromatographic results can be seen in the highly complex patterns from pyrolysis gas chromatograms of polymers.[18] Polymers were identified or recognized in poor resolution GC through the presence of functional groups such as olefin, aromatic, amide bonds, carbonyls, and others. Such methods of data analysis may be expected to be beneficial in biomedical and medical applications of GC. One example of a successful application of chemometrics in biochemical measurements was demonstrated for urinary organic acid profiles and uterine cervical cancer.[19] In this work, a total of 50 organic acids from urine samples (0.25 mL) were resolved by GC and discriminant (cluster) analysis was performed on the GC data using 16 acids as the variables for discriminating between the two groupings. Discriminant analysis applied to these 16 variables correctly classified 26 urine samples into two separate clusters according to tumor types in the canonical plot.

Advanced data handling of gas chromatographic data has been used in microbiology where the volatile fatty acids in bacteria, long a reliable method to type bacteria through chemotaxonomy,[20] were characterized by GC. The data, when treated by chemometrics allowed subgrouping of 169 coagulase-negative staphylococci collected during an outbreak of nosocomial sepsis in a hematologic unit.[21] Their findings corroborated the results from conventional typing methods showing

Table 3 Examples of multivariate analysis methods and applications with GC data

Sample	Refs.

similarities in strain characteristics and, therefore, the same epidemiological origin.

Multivariate analysis methods then, are powerful tools to extract from gas chromatograms details that otherwise elude the unaided eye simply owing to the complexity or subtlety of the data. This is especially so with natural materials such as food odors or vapors. Several more examples are listed in Table 3.[22–31]

3.2 Neural Network Analysis in Gas Chromatography

Another approach to comparing complex chromatograms through what may be nonsubjective computational tools is that of neural network analysis. In all neural networks, the software is used to mimic the human ability to discern patterns. In contrast to humans, computers can operate without fatigue and can survey large amounts of data without the time restraints that humans experience. In neural network methods the network learns to recognize data from known samples. In practice, the chromatogram or the intensity versus retention time pattern of the chromatogram are entered into the input layer after which hidden neuron layers establish weight factors that form a correct answer for the known sample. Other known samples can be trained so that other answers are obtained and an overall weight factor for each neuron in each layer is created, providing that the network properly learns the differences between samples. Thus, unknown samples should be rapidly categorized when chromatographic results for an unknown sample are presented to the trained network. This is especially helpful when the chromatograms are complex and defy reasonable comparisons by humans.

Neural networks have been used in situations where the samples are complex and differences might be due to nonlinear causes. This is especially important in instances where uncertainty exists when two complex mixtures are combined and is illustrated nicely with the recognition of Arochlors in environmental samples.[32] In this approach, a simple architecture was developed in which ~10 peaks were used to classify samples on the basis of the level of Arochlor contamination in environmental samples.

In another example, neural networks were used to classify vegetable oils after GC analysis of samples for methyl ester derivatives of fatty acids[33] and to assign botanical origins of vinegar samples.[34] Polyalcohols, rather than volatile chemicals, were found useful in recognizing the country of origin of various vinegar samples. A similar use of neural networks and GC data from pyrolysis analysis of hashish was found successful in discriminating between hashish obtained from different sources.[35] Lastly, defects in milk were screened using neural network analysis with GC results.[36]

Unlike the traditional methods for interpreting chromatograms, these advanced methods can be expected to undergo further refinements in the years ahead. They do, however, establish a basis from which automated data reduction can be successfully completed and used as a powerful tool in the utilization of GC data.

4 FUTURE DEVELOPMENTS

The current standards for data processing in chromatographic systems afford a high level of convenience and precision in qualitative and quantitative determinations; these meet or exceed the analytical needs for resolving power of contemporary columns. Nevertheless, the technology is rooted in principles that have been long a part of GC separations and these may be expected to continue well into the future. In contrast, the methods necessary to compare analytical findings for a large number of samples are in nascent stages of application. The methods are developed but not well advanced in daily applications. These chemometric methods may be expected to undergo refinement and general adoption during the next decade. This may be especially so in view of the growing and now major emphasis placed on biomedical chemistry.

LIST OF SYMBOLS

t_r	retention time
η	asymmetry factor
t_m	retention time of unretained solute
K	partition coefficient
β	phase ratio for a column
C_g	concentration of sample in gas phase
C_l	concentration of sample in liquid phase
w	peak width

ABBREVIATIONS AND ACRONYMS

ECD	Electron Capture Detector
FID	Flame Ionization Detector
GC	Gas Chromatography
GC/MS	Gas Chromatography/Mass Spectrometry
MS	Mass Spectrometry
2-D	Two-dimensional
3-D	Three-dimensional

Hyphenated gas chromatography (GC) refers to not only the coupling of a GC to information-rich detectors but also the coupling of the gas chromatograph to automated sample preparation techniques. Examples of information-rich detectors include mass and infrared spectrometers, whereas automated sample preparation techniques include solid-phase microextraction (SPME), large-volume injection (LVI), purge and trap (PT), headspace (HS), and gas chromatographic approaches. The gas chromatographic approach involves the wedding of two gas chromatographs and is commonly referred to as multidimensional gas chromatography (MDGC). The union of the automated sample preparation techniques with MDGC and information-rich detectors affords the capability for quantitative and qualitative analysis of a wide variety of sample matrices for analytes at parts per billion (ppb) concentrations. However, not every hyphenated configuration is worth considering, and careful matching of the hyphenated approaches is essential to obtain the maximum analytical benefits.

1 INTRODUCTION

Hyphenated GC has for the most part traditionally referred to the coupling of a powerful separation technique, namely capillary GC, with powerful information-rich detectors such as mass spectrometry (MS) or infrared spectrometry (IR). The term ''hyphenation'' was first popularized by Hirschfeld in 1980.[1] However, more properly, hyphenated GC should refer to not only the coupling of GC with information-rich detectors but also the coupling of GC to novel automated on-line sample preparation techniques such as PT, static HS, LVI, and SPME. Likewise, the wedding of two gas chromatographs, referred to as MDGC can easily be classified as a hyphenated gas chromatographic technique. In this case, the separation power of at least two gas chromatographs with columns of different separation capabilities is brought to bear. It now becomes readily apparent that the merger of advanced sample preparation techniques with potent information-rich detectors in conjunction with the separation capabilities of capillary GC provides for a powerful analytical approach for the analysis of volatile and semivolatile compounds.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

The union, for example, of LVI with MDGC and MS can provide an analytical technique that has detection limits from ppb to parts per trillion (ppt), with typical precision of ±10%. In a similar fashion, the union of MDGC with IR and MS can provide both qualitative (structural) and quantitative (amounts) of target compounds in very complex mixtures such as natural product extracts. The union of SPME with GC and MS can afford the capability for the analysis of ppb levels of target compounds in environmental samples. The underlying theory to hyphenated GC, that is the union of GC with information-rich detectors and automated on-line sample preparation techniques, rests with the fact that the information gained from the data generated by a GC hyphenated approach possesses the potential to be several orders of magnitude more powerful and useful than that obtained from employment of the techniques separately. This does not mean that every hyphenated technique is worth using or even considering. For example, coupling a GC fitted with a column having inadequate separation capabilities with an MS defeats the purpose of the technology. Thus, adequate thought as to the distinct advantages of each component of the marriage must be carefully considered before confirming the union. In other words, thoughtful and careful matching of hyphenated approaches is essential to the realization of the desired benefits.

The combinations possible using only a few mergers of GC separation with on-line sample preparation and detectors are almost endless, particularly when additional separation techniques such as liquid chromatography (LC), supercritical fluid chromatography (SFC), and capillary electrophoresis (CE), as well as additional detectors such as inductively coupled plasma mass spectrometry (ICP/MS), are coupled to a GC. For the purposes of this account, the sample preparation techniques (i.e. pre-GC) discussed are SPME, static HS, PT, LVI, and MDGC. The information-rich detectors (i.e. post-GC) discussed are MS (unit mass and high resolution) and IR (vapor phase (VP) and matrix isolation (MI)).

2 PRE-GAS CHROMATOGRAPH AUTOMATED ON-LINE SAMPLE PREPARATION TECHNIQUES

Sample-enrichment techniques in chromatographic analyses are generally employed because the concentration of the analyte of interest is below the detection limit of the analytical instrument. In some other cases the analyte must be removed from its matrix because introduction of the sample matrix would not be compatible with the desired chromatographic technique. In either case, the analyte must be accumulated in some fashion. This is usually accomplished by transferring the analytes from the parent matrix into or onto another matrix having a well-defined character which is compatible with the chromatographic procedure.

2.1 Solid-phase Microextraction

The information presented for SPME theory and practice is a concise summary of a comprehensive treatise of the topic covered by Pawliszyn.[2] SPME is fundamentally a solvent-free sample preparation/enrichment technique having qualitative and quantitative potential. A relatively thin film extracting phase of very small volume, $\leq 1\,\mu L$, is firmly coated and bound to a fused silica fiber which in turn can be exposed to a sample matrix. The sample matrix can be room air or aqueous solutions and in some limited cases organic solvents. The extracting phase bound to the fiber is, in a large number of cases, very similar to the phases employed in capillary GC technology. Polar or nonpolar phases such as poly(dimethylsiloxane) (PDMS) and carbowaxdivinylbenzene (CWDVB) and combinations of each can be employed.

The most convenient configuration of SPME technology is depicted in Figure 1. The thin fragile fiber is housed when not in use inside a tube-like structure, which is reminiscent of a GC syringe needle. Exposure of the fiber to the sample matrix of interest is effected by gently sliding the fiber outside of the housing and into the matrix. This exposure can be performed manually or automatically and both devices are available from Supelco, Inc. (Bellefonte, PA, USA). The partition coefficient of the analyte of interest between the sample matrix and the fiber coating material governs the amount of analyte extracted by the fiber coating. Obviously then, an analyte equilibrium can eventually be established between the sample matrix and the fiber. This behavior renders the SPME approach ideal for quantitative analysis. Furthermore, the presence of a very small amount of coating, which in turn removes very small amounts of analyte, is not likely to alter the sample matrix to any significant extent. SPME can also be used in qualitative analyses by employing a variety of coatings varying in polarity.

From a quantitative perspective, the mass of analyte extracted by the coating is linked to the equilibrium of the analyte in a three-phase system defined by the sample matrix (such as water or air), the fiber coating, and the HS of the sample (Figure 1). Assuming control of the volume of the fiber and its coating, the HS, and the sample matrix, placement of the fiber is not critical. Thus, extracts of the HS above a sample of interest or extracts of the matrix itself can be obtained.

Figure 1 Description of an SPME extraction device.

Consequently, direct contact of an SPME fiber with a well-defined sample configuration can lead to quantitative results.

Several extraction parameters have been documented as having meaningful impacts on qualitative and quantitative aspects of the amount of analyte extracted by the fiber. These include fiber conditioning, fiber type, exposure time and location (liquid or HS), temperature, salting (sample ionic strength), pH, and agitation.[2–6] There are, thus, some practical steps that can be taken to optimize each of these parameters to the benefit of the desired end result. To a first approximation, selection of the fiber type can be governed by the age-old adage that ''like dissolves like''. For example, if polar analytes such as flavor compounds are of interest, then a polar material such as CWDVB would be a logical first choice. A combination of temperature with exposure location can be used to an advantage. For example, sampling of the HS above a particularly complex matrix at increased temperature could possibly reduce the complexity of the materials extracted by the fiber. Adjustment of the pH of an aqueous sample can alter the nature of the species in solution and thus alter the extraction performance of the fiber. Adjustment of the ionic strength of an aqueous sample with the addition of simple ions from salts such as NaCl can bring about the salting-out phenomenon, thereby improving the performance of the fiber towards the analyte of interest. Agitation of the sample through sample stirring in liquid cases improves the performance of the SPME fiber; likewise, use of fiber vibration also improves the performance of the fibers, particularly as it relates to required sampling times. It should be mentioned here that control of the sampling time is very critical in obtaining reproducible results. Autosamplers can control sampling times to the second, thus excellent precision can be obtained even though equilibrium has not yet been reached.

The successful implementation of SPME technology rests in large part on a properly conditioned SPME fiber. Failure to properly condition an SPME fiber can result in unacceptable accuracy and precision. Fortunately, proper conditioning parameters have been well established for all of the commercially available SPME fibers, and these should be followed to the letter to ensure acceptable performance of the fibers. During use, fibers should be periodically examined closely, usually employing a microscope to ensure that no loss in phase coating has occurred through use.

2.2 Solid-phase Microextraction/Gas Chromatography

Having now established basic theories surrounding SPME, there are some operating principles associated with effective coupling of SPME to GC that must be addressed. Most SPME applications have been developed for GC, with a few applications for high-performance liquid chromatography (HPLC). The successful interfacing of SPME to GC, to produce the hyphenated technique SPME/GC, rests with the theory that analytes captured on the nonvolatile thin film can be efficiently thermally desorbed in a reproducible fashion. This process can be viewed as the reverse of extraction from a sample matrix. To accomplish desorption effectively and reproducibility, a high carrier gas linear velocity coupled with an increased temperature must be consistently established. Furthermore, the time for desorption must be carefully controlled even though theory would indicate that desorption times of seconds at 200 °C should be sufficient for most volatile or semivolatile analytes.[2]

Standard GC injection ports, such as split/splitless, can be effectively applied to the reproducible thermal desorption of analytes from an SPME fiber. One slight modification of the inert injection port liner is required to ensure the necessary linear velocity around the fiber. In general this involves changing the standard split/splitless liner of 3–5 mm internal diameter (i.d.), for a liner having an i.d. of approximately 0.8 mm and operating the injection port in the splitless mode. This small change results in an injection port volume change in approximately 3 s for the 0.8 mm linear compared with 44 s for the 3 mm liner. Such a dramatic change positively influences the desorption process, resulting in analytes being effectively transferred to the GC column in a narrow band. Additional ways to produce analytes in a narrow band include using a capillary GC column with a thick film stationary phase or cryofocusing the analytes at the front of the GC column using subambient GC oven temperatures. Rapid injection of the needle and simultaneous exposure of the fiber also facilitate the concentration of analytes in a narrow band. The formation of a focused narrow band of analytes directly effects the performance of the separation, either maintaining or reducing the maximum resolution of the GC column.

2.3 Automated Solid-phase Microextraction/Gas Chromatography Application

The enantiomeric distributions of volatile components in essential oils can be accurately and precisely determined using automated SPME/GC.[2,7] Employing a PDMS SPME fiber of 7 μm film thickness, a GC fitted with a column capable of separating optical isomers and an MS as detector, the optical isomer distributions in a grapefruit and a lavender essential oil were determined (Figure 2). The approach was relatively simple, involving automated sampling of the HS above the essential oil samples contained within a sealed 1.8 mL sample vial. The results obtained from the SPME approach were very precise having an average percentage relative standard deviation (RSD) of less than 6. The results were also accurate, agreeing very well with earlier findings using a heartcutting GC approach. The accurate and precise results were obtained without establishing equilibrium conditions, because such essential sampling parameters as fiber exposure time, sample HS volume, fiber desorption temperature, and sample temperature were carefully controlled. Likewise, evaluations of selected fiber types were conducted until the nonpolar fiber PDMS was found to yield reproducible results.

2.4 Headspace/Gas Chromatography

HS analyses using GC can be subdivided into three general categories.[8–12]

1. The sample for chromatographic analysis is obtained from a closed vessel where the material under investigation is caused to come into equilibrium with its vapor at a specified temperature. Once equilibrium is established the concentration of the analyte does not change with time if the temperature is held constant. When a sample is taken from the ''static HS'' of an isothermally sealed vessel the equilibrium is altered. Thus, the procedures associated with taking a sample must be reproducible.
2. The sample for chromatographic analysis is obtained from a gas stream which has been purged through the sample matrix, usually water. The purge gas, now

laden with the analytes, is usually passed through a trap which is inert to the purge gas but capable of efficiently capturing the analytes. Once trapped, the analytes are usually thermally desorbed onto the GC column. This PT approach is limited by some extent to the capacity of the trapping matrix, thus breakthrough volumes must be carefully established.

3. The sample for chromatographic analysis is obtained from a gas stream that has been passed over the sample matrix, such as soil or over the top of a water sample. As expected, the gas stream in this case is much less efficient when compared to the approach described in category 2 above.

2.5 Static Headspace/Gas Chromatography

Static (equilibrium) HS analysis is based on the theory that an equilibrium between a condensed phase and a gaseous phase can be reproducibly established for the analytes of interest and that the gaseous phase containing the analytes can be sampled reproducibly. Naturally, this approach will not be very successful when the analytes of interest possess very low vapor pressures because very little of the analyte will be found in the gaseous phase. Elevated temperatures, changes in pH, and the presence of additional electrolytes can in certain cases be employed to increase the analyte vapor pressures.

When coupling the static HS sample-enrichment approach to a GC, several key details and parameters must be carefully attended to. The combined instrumentation usually consists of two individual units, the static HS unit and the GC with appropriate detector. The two units are connected via a thermally controlled inert transfer line that serves as a source of carrier gas for the GC as well as a mode for the transfer of the analytes from the static HS unit to the GC column. In some cases, the two units are also linked and synchronized for automated sample preparation and analysis by software programs available from the manufacturers. Flow control and purity of the carrier gas are essential. Flow is normally controlled in the HS unit employing flow control valves. As the basic premise of static HS experiments rests with the presence of a thermally stable sealed environment, providing a leak-free thermally stable instrument configuration is fundamental to the successful operation of the system. All commercially available static HS systems have detailed descriptions of processes necessary to ensure a leak-free environment. Accurate and durable thermocouples are also provided.

The operation of the instrumentation usually follows the following sequence of events. Appropriate carrier gas flows and temperature zones are established. Additional carrier gas flow is initiated to sweep the lines, sample loop, and needle. A sample in a sealed vial is allowed to equilibrate at an elevated temperature for a specified length of time (Figure 3). The sealed sample vial is raised onto a needle that punctures a septum and pressurization gas fills the vial to a predetermined level. The vial is allowed to equilibrate for a relatively short time to ensure complete diffusion of the pressurization gas with the sealed sample vial's atmosphere. A vent valve is opened and the pressurized contents of the sealed sample vial exit the system through a thermally controlled sample loop of previously selected volume, usually $\geq$1 mL. The vent valve is then closed and the contents of the loop allowed to equilibrate for a specified time. Next a multiple port valve is activated, placing the sample loop in the carrier gas stream. The carrier gas then sweeps the contents of the loop through the heated transfer line and into the GC. Usually upon initiation of sample transfer to the GC, instrumentation software is employed to automatically begin the chromatographic separation and data collection. Automated multiple sampling configurations can be employed that will perform repetitive analysis of multiple vials, essentially repeating the steps outlined above.

From the description of the operation and sequence of events outlined above for the static HS/GC experiment, an appreciation of the number of possible variables can be obtained. Thus, successive samples undergoing incremental changes in a number of static HS parameters could be used to optimized the analytical procedure. The parameters that are manipulated in order to optimize the procedure include times, temperatures, and pressures associated with sample heating, sample equilibration, loop fill, loop equilibration, and sample transfer. In some cases, manufacturers will provide software that allows for automated systematic changes in these and other key parameters, leading to an optimized approach.

2.6 Dynamic Headspace (Purge and Trap)/Gas Chromatography

The fundamental underlying tenet governing dynamic HS (i.e. PT) analysis, is that the change in the mass of a volatile or semivolatile analyte with time can be expressed in terms of the volumetric flow rate of a stripping inert gas.[9] That is, it is physically possible to strip volatile and semivolatile compounds from solid or liquid matrices by passing an inert gas over or through them and that the amount of material stripped can be related to the amount of gas passed through the matrices. Coupling this physical behavior with the capacity to trap the stripped materials on an inert trapping media affords an excellent opportunity for sample enrichment. Several important assumptions underlie the acceptable performance of PT:

- the concentration of the analyte in the stripping gas is equilibrated with the concentration in the condensed phase;

Figure 3 A typical sequence of events in static HS analysis. (Reproduced courtesy of Tekmar Instrument Company.)

- the liquid or solid matrix is essentially nonvolatile;
- the distribution constant of the analyte is not dependent on the analyte concentration.

The issues associated with coupling a PT unit to a GC are very similar to those described above for the coupling of a static HS unit to a GC. The two units are connected via a thermally controlled inert transfer line that can serve as a source of carrier gas for the GC as well as a mode of transfer for the analytes from the PT unit to the GC. Most often the PT and GC units are linked and synchronized for automated sample preparation and analysis. A leak-free environment is critical with PT as well as thermal stability.

The manipulation of the instrumentation follows the general sequence of events described below. Carrier gas flow compatible with the GC is established and temperature zones are equilibrated. In PT techniques, the system is not sealed as in the static approach, thus the HS above the sample need not come to equilibrium. Instead, the sample is placed into a chamber, at a preselected temperature, that is sparged with carrier gas at a specified rate and time (Figure 4). The sparging may take place by allowing the carrier gas to pass through a liquid or solid or over the HS above the liquid or solid. The sweeping carrier gas removes the analytes from the matrix and transports them under a thermally controlled

Figure 4 Typical instrument configuration for PT. (Reproduced courtesy of Tekmar Instrument Company.)

environment to a trap. The trap is usually allowed to come close to room temperature prior to transfer of the analytes. After a specified time has elapsed the sparging is stopped. It is important to note here that the characteristics of the solid sorbent material contained within the trap can vary over a wide range. The amount and type of trapping material is usually preselected, based on the types of analytes under consideration. Once the analytes have been stripped from the matrix to the trap, a multiple port valve is activated and the trap is heated and backflushed, thereby desorbing the analytes from the sorbent material and transferring the analytes to the GC through the heated transfer line. The GC column can be cryocooled below ambient temperatures to facilitate the capturing of the analytes in a narrow band at the head of the GC column. Once the transfer of the analytes to the GC is complete, computer software programs can be employed to begin the GC analysis. During the chromatographic separation process the temperature of the trapping material is normally raised to a value slightly higher than the desorption value. This increase in temperature cleans the sorbent material of residual material and renders the trap ready for the next sample.

To optimize the analytical procedure for target analytes, most instrumentation is equipped with the capacity to systematically increment the salient PT parameters.

The parameters that may be manipulated in order to optimize the procedure include: sample purge time, carrier gas purge flow rate, and sample temperature. Although not under the control of the instrumentation, a number of other parameters have significant impacts on the PT experiment. Among these are the sample size and the choice of the trapping media. In general, increasing the amount of material to be sparged will increase the amount of analyte captured on the trap. There are some practical limits to this approach, most of which are dependent on the character of the sample matrix. For example, too much solid material could possibly retard the efficient flow of stripping gas. Likewise, increasing the amount of a liquid sample that possesses some foaming characteristics may result in contamination of the system with undesirable sample matrix components. The most popular adsorbent for the enrichment of trace volatiles and semivolatiles from different matrices is Tenax™ GC. Tenax™ GC is an organic polymeric material, poly(2,6-diphenyl-*p*-phenylene oxide). The retention of unsaturated and polar material on the Tenax™ GC is such that the material has found wide applications in environmental analyses, flavor analyses, biological fluids, and human volatiles. The thermal stability of Tenax™ GC at temperatures of approximately 350 °C coupled with its low affinity for water further substantiate it as a very acceptable and usually the preferred trapping medium for analysis of volatile and semivolatile organic compounds by PT techniques.

Thus, by way of comparison, dynamic HS techniques/gas chromatographic techniques afford powerful applications in the areas of the qualitative and quantitative analyses of trace levels of volatile and semivolatile materials. Conversely, static HS/GC techniques afford powerful applications in the areas of qualitative and quantitative analyses of minor volatile and semivolatile components.

2.7 Applications of Static and Dynamic Headspace Gas Chromatography

The chemical composition of essential oils has been shown to be related to a variety of factors including age, genotype, and geographical growing locations.[13,14] In an application of static and dynamic (i.e. PT) HS techniques, quantitative and qualitative differences in the distribution of components in an essential oil were documented (Table 1). Through the use of an information-rich detector, MS coupled to the GC, qualitative information on two sources of coriander oil was obtained. Quantitative percentage distribution values for the components of the two were gathered using a flame ionization detector (FID) coupled to a GC. Both the static and dynamic HS approaches were successful in detecting statistically significant differences in the two coriander oils. In addition, both approaches agreed on the major components of each oil, as well as the relative distribution of each component. The precision of the static HS approach was found to be slightly better than that of the dynamic approach. The use of the MS and FID detectors allowed for the determination of sample 1 as an aged sample due to the presence of increased amounts of the linalool oxide, known to increase in aged essential oil samples.

Table 1 Quantitative comparison by component percentage distribution of two coriander oils by static and dynamic HS analyses[13]

Component	Dynamic		Static	
	Sample 1	Sample 2	Sample 1	Sample 2
α-Pinene	4.52	0.43	5.64	0.81
β-Pinene	0.52	1.77	0.20	1.29
Myrcene	0.26	2.76	0.49	1.19
γ-Terpinene	0.00	3.96	0.00	2.14
cis-Linalool oxide	3.14	0.29	0.20	0.22
trans-Linalool oxide	2.77	0.22	3.54	0.35
Linalool	81.70	77.55	84.35	80.95
Camphor	3.91	4.56	4.31	6.22
Geranyl acetate	0.25	2.25	0.19	1.47
β-Caryophylene	0.53	0.59	0.96	1.23

2.8 Large-volume Injection/Gas Chromatography

The injection system of a gas chromatographic system is designed to introduce accurately and reproducibly a small representative amount of the sample being investigated into the column without degrading the maximum separation efficiency of the column.[15,16] The most common injection techniques are split, splitless, and cold on-column. Split injection is normally employed for minor component analysis where the solute concentration in the sample is present at concentrations greater than 50 ppm (50 ng μL^{-1}). The splitless injection technique, if properly implemented, is most frequently used for trace component analysis in the range from 0.1 ppm to 200 ppm. Cold on-column injection allows the sample to be deposited directly onto the front of the column and has an applicable concentration range similar to the splitless technique. The major advantages of the cold on-column technique are twofold. First, the sample is not subjected to the high temperatures required for split and splitless injections that could cause analyte decomposition or artifact formation. Second, as an intermediate flash vaporization step is not present, discrimination of higher-boiling components is minimized. A further

limitation of these three most common injection techniques is that the sample volume is limited to less than 2 μL. Vogt et al.[17] developed another technique, programmed temperature sample introduction (PTV) that overcomes the 2 μL constraint and allows a larger aliquot of the sample analytes to be deposited onto the column while simultaneously eliminating the solvent. This injection technique is now more commonly referred to as LVI.

Figure 5 is a diagram of a PTV inlet. The PTV inlet closely resembles the classical split/splitless inlet as the sample is deposited in a liner. The carrier gas enters the liner at the top and exits at the bottom, and a solenoid valve allows for switching between split and splitless operation. A functional difference between the PTV inlet and a split/splitless inlet lies in the temperature control. Conventional split/splitless inlets normally operate at elevated temperatures (>200 °C) where the sample is flash vaporized before entering the column. Although the PTV inlet can operate under these elevated isothermal temperatures, it is also capable of rapidly heating or cooling the liner. Heating rates in excess of $10\,^{\circ}C\,s^{-1}$ and subambient cooling are common. Operationally, the sample is injected onto the inlet liner, usually at a temperature below the boiling point of the solvent. The inlet is then rapidly heated to transfer the sample from the liner to the front of the column in a very narrow band, thus preserving the separating power of the column. The capability of introducing the sample into the inlet at lower temperatures affords numerous advantages and are similar to those described for the on-column inlet.

The most important feature of the PTV is the capability for ultratrace analysis (i.e. sample concentrations below 1 ppt) via the introduction of sample aliquots up to 1 mL. This is accomplished by operating the PTV in the solvent venting mode. The preferred implementation of this is referred to as SVSF. The chromatographic events are divided into five time zones and are described below.

Figure 5 Diagram of a PTV inlet system. Flow paths are shown for the solvent venting–stop flow (SVSF) configuration. (Reproduced courtesy of Jerstel GmbH and Co.)

1. *Pre-injection* The split valve is open, GC and inlet temperatures are at initial values and the column head pressure is at normal operating pressure.
2. *Sample injection* Immediately before the sample injection the column head pressure is reduced to ambient (stop flow). The sample is injected onto the inlet liner at a slow constant rate defined by the solvent boiling point, solute vapor pressures, inlet temperature, and gas flow rates. Injection speeds of $50\,\mu L\,min^{-1}$ are not uncommon, resulting in 10 min to inject 500 μL. During this time the inlet conditions are such that the solvent vaporizes and is swept from the inlet liner. Solute molecules, possessing lower vapor pressures (higher boiling points), remain in the liner as a liquid or solid.
3. *Post-injection* The syringe needle is withdrawn from the inlet and the run-time clock starts (time zero). The inlet conditions of stop flow remain in effect, allowing further purging of the remaining solvent.
4. *Sample transfer* The column head pressure is restored to normal operating pressure and the split valve is in the splitless mode. The solutes are transferred onto the column by rapidly heating the inlet liner.
5. *Sample analysis* The GC temperature program starts and, after appropriate times, the inlet returns to the split mode and then starts its cool down to the initial temperature.

A prerequisite for proper quantitative analysis via LVI/GC requires the vapor pressures of the solutes being analyzed to be significantly higher than that of the solvent. Failure to meet these conditions will result in a nonreproducible loss of solute and poor precision. Optimizing the injection speed relative to temperature, flow rates, and vapor pressures cannot be underestimated if precise quantitation is required. Also, a constant slow injection at a definable rate requires the addition of a computer-controlled injector. These injectors are commercially available.

2.9 Applications of Large-volume Injection/Gas Chromatography

GC is routinely used for the analysis of many environmentally significant assays.[17,18] The determination of trace components in water usually includes sample preparation steps that enrich the analytes and remove the matrix. The sample enrichment is frequently a time-consuming and labor intensive operation. Elimination of the sample enrichment process would not only decrease analysis

costs and increase sample throughput (via automation), but would also increase the precision of the method. LVI successfully addresses these concerns by both directly injecting the water without preconcentration and by incorporating an in-vial extraction of the water into an organic solvent. Other categories, such as the analysis of beverages, have found significant assay improvements using LVI techniques.

2.10 Multidimensional Gas Chromatography

High-resolution GC incorporating capillary columns is capable of separating and quantifying hundreds of compounds in a single run and has been used for the analysis of complex mixtures such as natural products, biological fluids, and environmental samples since the early 1960s.[19–22] Depending upon the analytes of interest, even the optimum GC system cannot resolve all of the components in a simple mixture of less than 10 compounds. In addition, as GC detectors such as FID and MS have improved by decreasing detection limits, analysts have come to realize that almost every peak in a GC chromatogram of a complex mixture is most probably a combination of more than one component. MDGC was developed to address this situation. In its simplest form MDGC is defined as a GC system of two or more columns of different selectivity and a device that enables the selective transfer of a portion of a chromatographic run from one column to the second column (a process known as heartcutting). The incorporation of columns of different selectivity is imperative as columns of identical selectivity (stationary phase) would add little value toward increased resolution of analytes. In addition, the hardware used to effect the transfer should be inert with respect to the analytes of interest so as to maintain the maximum efficiency of the separating columns.

Numerous different hardware implementations of capillary-to-capillary heartcutting MDGC systems are commercially available. Most are based on pneumatic flow control first introduced by Deans[20] in 1968. A comparison of three different implementations of MDGC was presented by Gordon et al.[21] A diagram of one of these systems in a dual-oven configuration is shown in Figure 6. The operation of a typical MDGC system for heartcutting includes three basic operations:

1. An initial separation is performed on the first column (i.e. precolumn), without transfer of eluent to the second, or analytical, column.
2. The retention time windows (the run time immediately before to the time immediately after) for the analytes of interest are determined from retention times obtained from the precolumn separation. The sample is injected a second time onto the precolumn and, at the appropriate times, the solutes are heartcut to the analytical column.
3. Final separation occurs on the column under temperature program conditions.

Precise balancing of the pressures and volumetric flows of the MDGC system is paramount. Key components essential to the proper functioning of an MDGC system are a fixed restrictor and a midpoint restrictor. The fixed restrictor is normally a short length of narrow-bore (100–150 μm) uncoated deactivated fused silica column. The combined pressure drop of the fixed restrictor and the mid-point restrictor should be equal to that of the analytical column at normal operating conditions of

Figure 6 The flow paths of an MDGC system. (Reproduced courtesy of Marcel Dekker, Inc.)

temperature and flow. Failure to balance the pressures in this fashion will result in changes in the retention times on the precolumn during heartcutting, when compared to the initial separation performed without heartcutting, resulting in either incomplete transfer of the analytes of interest or transferring more of the precolumn eluent than desired. A cold trap situated in front of the analytical column serves to trap the heartcut material eluting from the precolumn as a relatively broad band into a sharp band, thus preserving the resolving power of the analytical column. Evaporating carbon dioxide or liquid nitrogen under pressure can be used as cryogenic materials.

As mentioned earlier, the selectivity of the two columns in the MDGC system should differ. For example, if a polar column such as polyethylene glycol is used as the pre-column, then a dimethylpolysiloxane-based analytical column is usually a good choice for the analytical column. Such differences in separation fundamentals multiply the effectiveness of the MDGC separation.

Computer control of the valve sequences necessary to perform an MDGC analysis is required for reproducibility. If the heartcut starts to early, other analytes could be transferred to the analytical column and potentially co-elute with the compounds of interest and, conversely, if the heartcut is initiated late, the compounds of interest may not be transferred to the analytical column. Precise control of numerous hardware operations is required to obtain reproducible results. These include:

- the timing of the heartcut valve;
- turning on and off the cold trap;
- the exact flow rate and opening and closing of the mid-point split valve;
- the start of the temperature programming of the analytical column oven.

Figure 7 Chromatogram of a tobacco smoke sample: (above) full precolumn (single-column) chromatogram, (below) an expanded view of the section indicated on the top chromatogram. (Reproduced courtesy of Preston Publications.)

2.11 Applications of Multidimensional Gas Chromatography

Most successful MDGC applications address many issues associated with both sample preparation and analysis.[23–25] Among the issues are:

- target compound analysis;
- use of precolumn to essentially replace classical fractionation of the sample;
- decreases in sample loss and artifact formation due to classical sample fractionation;
- total sample analysis via sequential heartcutting.

The application of MDGC techniques to target compound analyses in complex mixtures employs and addresses many of the issues listed above. For example, MDGC techniques were applied to the analysis of a target compound in rice and to tobacco smoke. The compound 2-acetyl-1-pyrroline has been determined in a crude complex rice extract. Sample preparation involved preparing a methylene chloride extract of the rice followed by injection of the crude extract into an MDGC system. Thus, no classical fractionation was required, eliminating any loss or artifact formation. Furthermore, total extract analysis by sequential heartcutting was available but not necessary for this application. Tobacco and tobacco smoke, like most complex mixtures, are known to contain hundreds of semivolatile components. A conventional single-column capillary gas chromatogram of a tobacco smoke sample is shown in the top of Figure 7. The bottom of this figure shows an expanded section of the full chromatogram. The section from approximately 52.5 min to 53.5 min appears to contain 2–4 peaks and mass spectral scans were able to identify an ethyl-substituted pyrazine as well as numerous unidentifiable

Figure 8 Analytical column chromatogram generated from the heartcut indicated on Figure 7. (Reproduced courtesy of Preston Publications.)

components. This same region of the separation was subsequently heartcut to a second capillary column resulting in the chromatogram shown in Figure 8. Mass spectral scans were able to confirm the presence of nine identifiable components.

3 POST-GAS CHROMATOGRAPH SAMPLE ANALYSIS TECHNIQUES

The underlying principle governing sample detection and analysis by GC is governed by well-defined consistent responses of a particular sensor (i.e. a detector) to the presence of an analyte within the detector's environment.[9–26] In GC, the presence of the analyte within the detector's environment is accomplished by the appropriate interfacing of the end of the GC column with the sensor of choice. Each detector will present its own set of requirements for successful interfacing to a GC.

The output of the detector is called a response, and there is a wide array of relationships between the characteristics of a detector and the characteristics of analytes. Generally, the amount of analyte within the zone of the detector governs the amount of the detector response. However, the chemistry of the analyte including, for example, its structure and stability, dramatically affects the ability of the detector to register a response.

In order of importance in a chromatographic system, the detector ranks a very close second behind the GC column. Scott[26] has listed seven major detector specifications that are important: detector linearity, linear dynamic range, detector noise level, detector sensitivity, pressure sensitivity, flow sensitivity, and temperature sensitivity.

Detectors are not universal linear devices. That is, detectors provide a linear response to changes in concentration over a definable range. This linear response usually takes the form of a linear plot of concentration on the x axis versus detector output on the y axis. In some cases the detectors for gas chromatographs can provide a linear response over a concentration range of more than two orders of magnitude. Once this linear range has been defined for the analyte of interest, then the linear dynamic range of the detector has been established for that analyte.

Detectors have a net response, that is, random changes in signal levels, even in the absence of an analyte. This random response is termed detector noise. Minimization of detector noise is critical to the performance of any system. When detector noise is minimized, detector sensitivity is improved. Detector sensitivity is defined as the minimum concentration of analyte that can be discerned from the random noise. Thus, if the noise is consistently low, sensitivity can be maximized. The degree of detector sensitivity to changes or fluctuations in pressure, flow, and temperature vary greatly depending on the detector. For mass spectrometers all three of these variables have a significant impact on detector performance. For FID, provided that the temperature is high enough to prevent analyte condensation, temperature changes are not as significant to detector performance.

A diverse array of detectors are now currently being used in GC applications. In a number of cases these detectors can be described as information rich. That is, not only do these detectors provide evidence for the presence of an analyte, but they also furnish structural information concerning the analyte. The two most popular detection systems fulfilling the requirements as information rich are MS and IR. The following sections will discuss the theory and instrumentation surrounding these two systems.

3.1 Gas Chromatography/Mass Spectrometry

Many of the basic principles governing the performance of a GC/MS system are those associated with gas flow and vacuum parameters.[27–33] The GC must operate over a wide range of gas flows and pressures whereas the MS must operate under reduced pressures. Calculations surrounding the optimization of these parameters associated with each component of the GC/MS system can be made; however, approximations provide for adequate values and detailed calculations are not required. Assuming that the mean free path of ions (i.e. the molecular flow) within the MS is sufficient and that the vacuum pumping speed is adequate to handle the incoming gas flow from the GC, then the successful wedding of GC with MS will be possible. There is a very practical reason for maintaining molecular flow. When molecular flow is established, molecule–molecule and ion–molecule reactions and interactions are virtually eliminated. A vacuum

in the range of 1×10^{-5} torr is normally required for most MS experiments. These types of reactions are undesirable in the GC/MS experiment because they have the potential for the production of additional molecules and ions that will complicate the molecular fragmentation patterns of the resulting data. Such complications will severely hinder the ability to interpret the resulting mass spectra.

Although not basic to the performance of a GC/MS system, the computer is a necessary component with which to realize the full potential of the GC/MS system. Thus, when speaking of current commercially available GC/MS systems, it is assumed that the actual system consists of a GC, an MS, and a computer (Figure 9). In most current configurations, the computer controls both the GC and the MS. Furthermore, the data collected from a GC/MS experiment is stored and can be evaluated employing software programs commonly available on most commercial systems.

The GC/MS interface provides an acceptable means by which the GC carrier gas with accompanying analytes eluting from the end of the GC column may enter the MS ion chamber under vacuum. When capillary columns are employed, the flow rate through the column is most often less than $3\,\text{mL}\,\text{min}^{-1}$. Thus, with current vacuum technologies all of the GC capillary column flow can enter the MS ion chamber with no sacrifice in the vacuum requirements. This capability is very advantageous in that all of the analyte present in the GC column can find its way into the MS ion chamber, thereby affording the potential for maximum sensitivity.

Two types of GC/MS interfaces, both with advantages and disadvantages, dominate those currently employed: direct and open split. With the direct interface, all of the analyte exiting the GC column enters the MS, thereby improving/maximizing sensitivity. From a practical hardware aspect, however, use of the direct interface requires that the GC/MS be vented should changes in columns be required. Venting of the MS requires exposure of the MS ion chamber to the room atmosphere. To prevent significant damage to the components in the ion chamber, which are very sensitive to air and water at elevated temperatures, this venting must be controlled and done only at room temperature. Failure to follow these procedures can drastically reduce the lifetime of many of the MS components to unacceptable values.

When open-split interfaces are used, changing a GC column does not require venting of the MS. In the open split configuration ample make-up carrier gas is supplied to the MS, thereby excluding the entry of air and water. Conversely, with the open-split interface, not all of the analyte exiting the GC column enters the MS ion chamber. This results in reduced sensitivity. Depending on the application this reduction in sensitivity may not present an issue for the desired analyte. Thus, use of a direct or open-split interface for GC/MS experiments should be evaluated on a case-by-case basis.

One of the fundamentally critical aspects of optimum performance of a GC/MS system rests with the proper installation of the GC column in the MS. Having properly conditioned the GC capillary column and established the desired carrier gas linear velocity, insertion of the end of the column directly into the MS ion chamber is possible. Very close attention must be paid to the proper insertion depth into the MS chamber. Manufacturers of GC/MS systems are very clear on the necessity of performing this step accurately. Improper installation of the GC column can lead to a complete absence of instrument performance.

To establish the necessary vacuum within the MS ion chamber receiving the carrier gas flow from the GC will often require the presence of two vacuum pumps.

Figure 9 Diagram of a GC/MS system.

A roughing pump and an ion chamber pump (usually a turbo or diffusion pump) comprise the dual pumps. Continuous monitoring the vacuum in a GC/MS system is important in assessing proper functions. With a properly installed capillary GC column having the dimensions 30 m long, 0.25 mm i.d., 0.25 μm film thickness, and a linear velocity of approximately 30 cm s^{-1}, the pressure in the MS ion chamber is approximately 5×10^{-5} mm Hg. This vacuum reading is adequate for proper functioning of most commercial systems. When installing a GC column in the GC/MS system, 12–24 h are normally required to achieve equilibrated thermal and pressure parameters.

After having established stable operating temperatures and pressures, mass spectrometers must be properly calibrated. Conveniently, GC/MS–computer manufacturers provide user-friendly software controlled procedures for calibrating the MS. Many quadrupole mass spectrometers are calibrated using perfluorotributylamine (PFTBA). Under computer control the MS is autotuned to target parameters associated with the mass spectrum of PFTBA. Manual tuning of the MS is possible, but is very time-consuming. The computer output from consecutive autotunes can be used to diagnose the performance and status of the GC/MS system. For example, systematic increases in the amount of multiplier voltage can indicate that the ion filaments are deteriorating. The presence of ions at $m/z = 18$ (water), 28 (nitrogen), 32 (oxygen), and 40 (argon) strongly indicates a leak in the system. The strong indication of a leak requires immediate attention or the GC/MS system performance will dramatically and rapidly deteriorate.

In the normal course of events, venting or shutting down of the GC/MS system will become necessary. Proper attention to manufacturer recommendations for shutting down the MS will prevent abnormal deterioration of the system. Depending on the type of ion-chamber pump employed, decreases of temperature or spinning speed will be required as part of the venting process. When and only when these requirements have been met is it safe to open the MS to the atmosphere and conduct the necessary repairs or changes. Should repairs extend for a period of time, it is important to protect the MS from exposure to dust and moisture. Once repairs or changes have been made then the MS may be pumped down and operations resume.

From a data acquisition perspective the GC/MS–computer system set-up affords many diverse options. In particular, the type of mass-spectral data gathered can be controlled through instrumentation settings. For example, the initial set-up for the analysis of an unknown mixture would most probably involve collection of the mass spectral data in the scan mode. Data collection in this manner provides a total ion chromatogram consisting of a plot of total ion response as a function of time. Data gathered in this way has qualitative implications. The response can be related to the number of ions present, this in turn having quantitative implications. In a second mode of data collection, data from only selected ions may be collected, yielding a selected ion chromatogram (SIM) consisting of a plot of the selected ion response as a function of time. This approach also has quantitative aspects.

From a qualitative perspective, a GC/MS–computer system represents a very powerful physical probe into the structure of analytes. Using the normal, essentially standard, instrumental system configuration settings for gathering total ion chromatograms in the scan mode affords the potential for searching mass spectral databases having more than 100 000 mass spectra gathered under the same standard conditions. Thus, should the GC separation provide for good resolution of the components of interest, automated searching of mass spectral databases (libraries) can furnish valuable data concerning the structure of the analyte. The mass spectra are generated through the fragmentation of the analyte under a well-defined set of conditions yielding ions. These ions usually have a charge of −1, thus the obtained plot of ion abundance versus mass to charge ratio, m/z, can be viewed as the mass spectrum of the component. The search can readily be accomplished by automatically submitting, via instrumental software programs, the mass spectrum of the unknown analyte for comparison against the mass spectra contained in the database. Most automated search routines will provide a match quality ranging from 0 to 100, with 100 being a perfect mass-spectral match. The instrumentation can also provide a graphical representation of the mass spectrum of the unknown analyte alongside that of the library spectrum. Very close examination of the output from the library search routines is mandatory to ensure accurate structural assignments. At this point, combination of the separation parameters from the GC with the results from the MS represents a very powerful analytical combination. That is, a combined assessment of both the analyte retention time and the analyte mass spectrum gives more confidence in the structural assignments. In addition, as the amount of ions present can be related to the amount of analyte present, quantitative analysis by total ion current (TIC) can also be realized.

Should quantitative analysis of a known component be the main thrust of the GC/MS experiment, then the instrumentation can be configured in the SIM mode. In this mode, only ions associated with the analyte of interest will be collected by the MS–computer system. This approach provides for increases in specificity and sensitivity. The specificity is improved because only ions associated with the analyte of interest are collected. For

the same reason, the sensitivity is increased because only a few ions, i.e. two or three, are being collected versus approximately 300–500 being collected in the TIC mode. Both internal standard and external standard calibration methods are possible with GC/MS instrumentation. Thus, GC/MS–computer instrumentation set to collect data in the TIC mode has powerful qualitative implications, whereas instrumental settings in the SIM mode have powerful quantitative implications.

All of the issues associated with applications associated with GC/MS are also valid when analyses are pursued with GC/high-resolution MS. Low-resolution instruments have been defined arbitrarily as those instruments that separate unit masses up to $m/z = 2000$. An instrument that can resolve two ions differing in mass by at least one part in $10–15 \times 10^3$ is generally considered a high-resolution mass spectrometer. For example, a mass spectrometer that can resolve an ion mass of 600.00 from one of mass 599.95 would have a resolution of 10 000. With this mass resolution capability the data from high-resolution mass spectrometers can be used to calculate the ion atomic composition. The possibility for high mass resolution is realized by the introduction of an electrostatic field after or before a magnetic field along the path of the ions. Ions are generated in the source and they are accelerated toward the analyzer. As the ions enter the magnetic field they are directionally focused. Upon entering the electric sector, which is perpendicular to the flow of the ions, the ions are again curved. This application of double focusing is the fundamental theory supporting the resolution capability of high-resolution MS.

3.2 Applications of Gas Chromatography/Mass Spectrometry

GC/MS currently finds a very wide array of applications including analyses of biological tissue, petroleum residues, pesticides, essential oils, and pharmaceuticals.[34,35] In one specific case, analysis for and speciation of street drugs has been accomplished using a GC/MS approach. Following derivatization with pentafluoropropionic anhydride (PFPA), GC separation with MS detection of isomers of the street drug MBDB was accomplished in 9 min. Interpretation of the MS spectral data assisted in determining the structures of the isomer. In some cases GC/high-resolution MS is employed to provide accurate mass confirmation of the presence of drugs of abuse.

Polychlorinated biphenyls (PCBs) are widespread toxic organopollutants. A method for qualitative and quantitative analysis using GC/MS for PCBs in soil has been developed. Advantage of the properties of MS is taken through the use of a ^{13}C-substituted PCB as an internal standard. The presence of the ^{13}C label in the PCB did not significantly affect the retention time of the PCB. Furthermore, the presence of the ^{13}C atoms in the PCB produced a unique mass spectrum having ions attributable to the heavier ^{13}C. These unique ions allowed for quantitation of the PCB levels in selected soil samples.

3.3 Gas Chromatography/Fourier Transform Infrared Spectroscopy

Two distinct analytical approaches that can be classified as gas chromatography/Fourier transform infrared spectroscopy (GC/FTIR) have dominated the recent literature. The techniques and instrumentation requirements for each approach are so significantly distinct as to require separate descriptions of the fundamental theory and hardware governing the successful application of each approach. In this light, the two GC/FTIR approaches are considered in independent sections.

3.4 Gas Chromatography/Fourier Transform Vapor Phase Infrared Spectroscopy

The fundamental theory underpinning the successful functioning of gas chromatography/Fourier transform vapor phase infrared spectroscopy (GC/FTVPIR) systems relies in large part on the ability to rapidly acquire multiple entire IR spectra in a very short time, i.e. four spectra per second.[36–42] This is possible because modern spectrometers employ a rapid scanning Michelson interferometer for measuring the IR spectrum. The rapid acquisition of spectral data is also a fundamental requirement because very low levels of components, nanograms, will pass through the IR beam in a few seconds with properly functioning capillary GC.

Following collection of the spectral data, Fourier transform mathematics converts the time-domain data, an interferogram, into frequency-domain data, an IR spectrum. This calculation is accomplished using a computer, due to the significant amount of data required to adequately represent the IR spectrum. Gram–Schmidt mathematics can also be performed on the spectral data to yield a total response chromatogram (TRC). A TRC is a plot of IR response versus time that is very similar in presentation to the plots obtained from MS response versus time, a TIC.

A simplified diagram of a GC/FTIR system can be found in Figure 10. The light from the IR source passes through the interferometer and then through a flow cell, i.e. a light pipe. Any light that passes through the flow cell is focused on a detector where the light is converted into an electrical signal. The electronic signal is ultimately converted, via computer-driven mathematics, into an IR spectrum. One end of the light pipe is inserted into the end of a capillary GC column. Thus, three operations are

Figure 10 Diagram of a GC/FTIR system. (Reproduced courtesy of Bio-Rad Company, Inc.)

occurring, simultaneously: IR light is continually passing through the light pipe, effluents from the GC column are entering and exiting the light pipe, and the detector is collecting the IR spectral data. At selected times only GC carrier gas is present in the light pipe, essentially when no analyte is exiting the GC column. Under these conditions an IR spectrum is taken which serves as a blank spectrum. A blank spectrum is essential for the mathematical calculations involved in the conversion of the interferogram to the IR spectrum.

From a hardware perspective, GC/FTVPIR has some unique requirements. A constant inert and dry purge gas, such as nitrogen, must continuously purge the optical system. Among the reasons for this obligation are:

- Exclusion of air, particularly carbon dioxide, from the optical path is essential due to its intense IR adsorption around 2250 cm^{-1}.
- Exclusion of water is essential because of its intense IR adsorption around 3500 and 1600 cm^{-1}, as well as water's ability to degrade the IR transmission properties of the KBr windows attached to the ends of the light pipe. Water will react with the KBr windows, resulting in the windows acquiring a frosted look, which severely hinders the transmission of IR light.
- Dry air will result in premature oxidation of the IR source.

The temperature of the optical path must be kept constant, $\geq$200 °C. Variations in temperature cause changes in sensitivity and changes in flow rates, not to mention subtle variations in the characteristics of the IR spectrum itself.

The light pipe with its KBr windows is the heart of the flow cell assembly. The inside of the glass light pipe is coated with gold to prevent the loss of IR light and provide as inert a surface as possible. The internal volume of the light pipe is approximately 100 µL with an i.d. of approximately 1 mm. Material eluting from the GC column enters one end of the pipe, passes through and exits the other end. As the material passes through the pipe, portions of the IR light are adsorbed, this phenomenon being captured by the detector.

Due to the relatively small diameter of the light pipe (1 mm), extreme care must be exercised in the proper alignment of the pipe itself, the parabolic mirrors of the IR light path, and the detector. All of these parameters can be optimized for maximum IR light throughput by monitoring the output of the detector while these objects are slightly moved. Maximum voltage output from the detector translates into more IR light throughput. Sequential adjustments of the objects will yield a maximum voltage indicating maximum IR light throughput. Once alignment is achieved, little to no further adjustments should be necessary.

Installation of the end of the GC column into the light pipe at the ideal position is essential for optimum performance of the GC/FTVPIR system. When the system is up and operational, IR light is continually passing through the pipe and causing the detector to output a certain voltage. Slow insertion of the end of the GC column into the light pipe from a side port can be made until there comes a point where the end of the GC column breaks the plane of the IR light beam, causing a change (drop) in the output voltage of the detector. The optimum position is, thus, the point of closest approach of the GC column end to the IR light beam without any interference. This location allows the GC column effluent optimum interaction with the IR light beam, thereby providing maximum sensitivity.

To obtain the necessary sensitivity from the IR detector, the mercury cadmium telluride IR detector must be cooled with liquid nitrogen. Most commercial systems provide IR detectors having Dewars capable of housing enough liquid nitrogen for 4 h. Thus, periodic checking of the detector liquid-nitrogen level is essential.

3.5 Gas Chromatography/Fourier Transform Matrix Isolation Infrared Spectroscopy

The successful operation of a gas chromatography/Fourier transform matrix isolation infrared spectroscopy (GC/FTMIIR) set-up depends on complete isolation of the effluent of a GC column at temperatures approaching

10 K in an inert noble gas matrix.[39,42–50] Complete isolation of the molecule in the matrix virtually eliminates all intermolecular interactions. In addition, molecular rotation is severely reduced at the very low temperature. Once captured at 10 K, usually in argon, maintenance of the temperature is fundamental to the success of the approach because the Fourier transform infrared spectroscopy (FTIR) spectra are gathered post-deposition. The availability of argon in which the analytes are captured is made possible by employing helium GC carrier gas containing approximately 5% argon. The presence of this small amount of argon in the GC carrier gas does not have any significant impact on the performance of the chromatography. At 10 K helium does not freeze and is hence pumped away via a diffusion pump–roughing pump configuration.

Figure 11 represents a simplified schematic of a GC/FTMIIR system. A description of the physical characteristics of the instrumentation is essential to a full understanding of the operation of the technology. The vacuum chamber denoted by the rectangle is fitted on top with a Pyrex™ window/O-ring for viewing the collection disk. The vacuum is provided by a diffusion pump and a roughing pump configuration. IR light from a Fourier transform spectrometer passes through specially designed windows as it reflects off a pair of dual parabolic mirrors, the collection disk, and a focusing mirror onto the surface of a mercury cadmium telluride detector. The detector must be cooled with liquid nitrogen. Positioning of the mirrors is very critical to the successful functioning of the GC/FTMIIR system. The optimum position of the multiple mirrors is accomplished in a way similar to the VP system by maximizing the voltage output of the detector under normal operating conditions. The optimization must take place under normal operating conditions because temperatures in the area of 10 K cause subtle changes in the position of the collection disk.

The collection disk is constructed of oxygen-free high-conductivity copper plated with hardened gold. The curved surface of the collection disk is highly polished to yield a uniform mirror finish. The surface of the collection disk serves as a platform for the collection of the effluent from the GC column from the GC transfer line. The effluent is the carrier gas, usually helium, containing about 5% argon as well as any analytes that may be present. When the effluent strikes the surface of the collection disk at 10 K the analytes and argon freeze on the disk and the helium is pumped away. Simultaneously, while the effluent is exiting from the transfer line, the collection disk is rotated at a predetermined rate. Thus, as the disk rotates the resultant physical phenomenon is a thin layer of argon on the surface of the collection disk. Close examination of this layer of argon reveals the presence of what appears to be a very fine transparent thread on the surface of the collection disk. Imbedded within the thread of argon are the analytes that have been separated by the GC column.

The position and characteristics of the GC transfer line relative to the surface of the collection disk are very important for the optimum deposition of the argon. The capillary GC transfer line protruding slightly from the heated nozzle (Figure 12) is made of deactivated fused silica of approximately 150 μm in diameter. The end of the GC transfer is positioned within approximately 150 μm of the surface of the collection disk. Incorrect positioning of the tip of the GC transfer line will result in an uneven/broken appearing thread of argon on the surface of the collection disk. More importantly, if the

Figure 11 Diagram of a GC/FTMIIR system. (Reproduced courtesy of Marcel Dekker, Inc.)

Figure 12 Drawing of the collection disk used in the GC/FTMIIR experiment showing the end of the GC transfer line protruding from the heated nozzle. Also illustrated is the argon thread. The dark marks in the thread indicated the position of solutes and correspond to the chromatogram at the bottom of the figure. (Reproduced courtesy of the American Chemical Society.)

tip of the GC transfer line is too close to the collection disk, contact between the two could result, scratching the surface of the collection disk. A scratched surface renders the collection of IR data impossible.

As the positioning of the collection disk is under computer control, the position of the disk relative to the IR light beam is always known. Thus, after a GC separation has been completed, exact positioning of the collection disk relative to the incoming IR light beam is possible. Analysis of the argon thread by FTIR takes place in the following way. The initial portion of the thread is scanned to establish a background. Then the disk is rotated at a predetermined rate while FTIR interferograms are rapidly taken and stored on the computer. After the entire run has passed under the IR beam, the data are converted into a plot of IR adsorption versus time. This plot is very similar to the Gram–Schmidt plot obtained from the Fourier transform vapor phase infrared spectroscopy (FTVPIR) experiment. The main difference is that in the FTVPIR experiment the data are collected in real time, whereas in the Fourier transform matrix isolation infrared spectroscopy (FTMIIR) experiment the data are collected post-run. To provide some assistance in determining the exact location of the argon matrix-trapped analyte on the collection disk, the instrumentation is fitted with an open split interface that allows a portion of the GC column effluent to be directed to a FID. The output from the FID is captured by the GC software, producing a trace of FID response versus time. The FID is a universal type of detector responding to most volatile and semivolatile organic compounds. Thus, the potential for correlating a FID response with an FTIR response is available with the instrumentation. The presence of retention times from the FID data also facilitates positioning of the collection disk directly under the IR beam such that the IR beam is focusing directly on the analyte of interest. For example, the response of hydrocarbons from the FID detector is normally relatively intense, at least with respect to the IR response that would be expected from a very low concentration of a hydrocarbon. Consequently, the FID would assist in locating components which may not possess strong IR-adsorbing chromophores.

Having captured the analytes in an inert noble gas matrix, coupled with the ability to hold them there for an extended time (hours), offers a distinct advantage to the matrix isolation (MI) experiment over the VP experiment. The VP experiment is a flow-through approach in which the IR data is gathered on the fly. In marked contrast, in the MI experiment the captured analytes can be examined over extended time. This capability translates directly into a tremendous improvement in sensitivity. Imagine possessing the capability of gathering IR spectra for as long as one wants. That is, the capacity for co-adding multiple numbers of scans of the analyte together with multiple scans of background spectra and subtracting the two. In practical terms this capability has afforded the capacity to collect FTMIIR spectra having excellent signal-to-noise ratios on as little as picogram quantities of material in a few minutes. Also, additional increases in sensitivity are realized because the lower temperature of the MI experiment versus the VP approach reduces the decomposition of thermally unstable molecules.

The lack of intermolecular interaction coupled with the virtual absence of molecular rotation, leads to IR absorption spectra from the MI experiment having significant and meaningful differences from IR spectra taken in other matrices. For example, narrow lines, frequently below 0.5 cm^{-1} for relatively small molecules, can be routinely obtained under MI conditions. Spectra such as these have been very useful in studying reactive molecules such as free radicals and reaction intermediates. Thus, the characteristics of the IR spectra obtained from an MI environment at extremely low temperatures would be expected to be very different from those obtained at elevated temperatures, such as VP experiments or even at room temperature. In the MI experiments, the ratio

of inert gas molecules to analyte molecules dictates the characteristics of the IR spectrum. This behavior is not unlike that observed as a function of concentration in solution room-temperature IR spectra. Acceptable ratios of about 5000 argon atoms to one analyte atom have produced excellent FTMIIR spectra using the GC/FTMIIR instrumentation.

Through a systematic investigation of a series of organic compounds possessing different functional groups, a relationship between the energy of selected band maxima as a function of matrix has been established. That is, the matrix in which the IR spectrum is taken significantly influences the energy and position of band maxima. For example, in the case of methyldecanoate carbonyl, absorption bands were observed at 1754, 1738, and 1769 cm^{-1} for the compound in an argon matrix, in the solid state, and in the VP, respectively. In general, the IR absorption maxima for compounds captured in an argon matrix were found to be intermediate between high values established by the VP experiments and low values established by IR spectra taken in the solid state. Likewise, statistically significant differences were also noted in IR absorption band maxima for organic compounds captured in a xenon or argon matrix. For example, the amide I band for diethylacetamide was found at 1661 cm^{-1} in a xenon matrix and at 1673 cm^{-1} in an argon matrix.

The virtual absence of molecular interaction and rotation in MI species afforded the capability of detecting a substantial difference in the IR spectra of *cis* and *trans* isomers in selected compounds. The elevated temperature of the VP experiment essentially eliminated any possibility of detecting this difference due to the relatively large widths of the absorption bands in the VP experiments. For example, the FTMIIR spectra of the *cis* and *trans* isomers of pinane were readily distinguishable one from the other.

3.6 Applications of Gas Chromatography/Fourier Transform Matrix Isolation Infrared Spectroscopy

Essential oils represent one of the more complex natural products having significant economic implications.[42] Determination of the structure of the components in these oils is paramount to effective assessment of their potential. For example (−)menthol, the major component of peppermint oil, is responsible for the major cooling effect known for peppermint. The other isomers of menthol, neomenthol, isomenthol, and neoisomenthol are structurally very similar to menthol but do not possess the cooling effect. GC/FTMIIR has been employed successfully to characterize the IR spectra of these compounds affording the capability to detect their presence in essential oils.

4 CONCLUSIONS

Within approximately two decades of the first coining of the term "hy-phen-ated",[1] hyphenated capillary GC techniques have become the methods of choice for the qualitative and quantitative analysis of complex mixtures.[51] Development efforts in modern GC-based instrumentation, depending on the integration of theories of GC, computers, and powerful information-rich techniques such as MS and FTIR detectors, have produced a wide array of very potent systems. Orchestration of combinations, such as on-line sample introduction, SPME, with GC, and MS, SPME/GC/MSD, has led to hyphenated systems with applications in a variety of areas. The enormous data sets generated from the information-rich detectors have been handled relatively easily with the advent of fast personal computers.

Future analytical hyphenated systems will most probably encompass the use of high-speed GC with accompanying high-speed mass spectrometers, infrared detectors and other specific detectors. Advances in hardware associated with on-line sample introduction approaches, such as SPME, LVI, MDGC, and HS techniques (dynamic and static) will assist in lowering further both the qualitative and quantitative limits of detection. Miniaturization of components should lead to additional systems being very compact and field deployable, with data transmission links directly to laboratory-based data analysis platforms. These advances should facilitate the collection of data followed by the rapid conversion of that data into information, and this new information into knowledge.

ABBREVIATIONS AND ACRONYMS

CE	Capillary Electrophoresis
CWDVB	Carbowaxdivinylbenzene
FID	Flame Ionization Detector
FTIR	Fourier Transform Infrared Spectroscopy
FTMIIR	Fourier Transform Matrix Isolation Infrared Spectroscopy

Instrumentation for gas chromatography (GC) comprises well-defined components, each of which contributes to the overall chromatographic performance. Most of these components have reached a mature level of technical development after nearly 50 years of development. Nonetheless, advances are occurring in an evolutionary, not revolutionary, manner with sample handling and in refinements of detectors. One area of dramatic advance in GC instrumentation is the development of small, sophisticated, portable gas chromatographs. Each component of a gas chromatograph (columns excepted) is discussed below where principles and recent developments are emphasized.

1 INTRODUCTION

The key parts of a gas chromatograph include: a source of gas as the mobile phase, an inlet to deliver sample to a column, the column where separations occur, an oven as a thermostat for the column, a detector to register the presence of a chemical in the column effluent, and a data system to record and display the chromatogram. In addition, some facility is needed so that temperatures of various components can be accurately known and controlled. These parts of a gas chromatograph have been unchanged in function or purpose for over the last 40 years although technology has been ever improving in design, materials, and methodology. In particular, analog electronics for control of temperature zones and data acquisition were replaced with digital electronics and interfaced with computers in the 1970s and 1980s. The arrangement of these components is shown in a block diagram in Figure 1 and this arrangement is common to virtually all gas chromatographs regardless of age, model or manufacturer. A modern gas chromatograph is shown in Figure 2. In the discussion below, the general function of each component is provided with comments on the status of the technology. Most descriptions of GC will include a cursory description of instrumentation; few will provide a detailed treatment of the instrumentation or technical details. Some of the best discussions of hardware can be found in publications released by instrument manufacturers.[1,2] Unfortunately, these may not be found routinely in libraries but the reward for efforts to obtain them is found in the useful details for optimizing an analysis or practical help for maintaining the instrument.

The column may arguably be considered the key component of a gas chromatograph and accordingly has been treated separately under another heading. However, the total variance of a separation (σ_T) will conform to principles of error propagation and be a sum of variances from the injector (σ_I), column (σ_c), detector (σ_d), and data system (σ_{ds}), i.e. $\sigma_T = \sqrt{(\sigma_i + \sigma_c + \sigma_d + \sigma_{ds})}$. Thus, each of these components contributes to the overall efficiency of a GC separation and merits individual attention.

2 CARRIER GAS

The carrier gas or mobile phase in GC is an essential, but limiting, facet in separations. Carrier gas is the means to move constituents of a sample through the column and yet the choice of possible gases is restricted. Moreover, the carrier gas has properties that sometimes can complicate an analysis. Unlike liquid chromatography (where a wide selection of mobile phase compositions may be possible),

Figure 1 Block diagram of gas chromatograph.

Figure 2 Photograph of modern gas chromatograph.

very little can be gained in separations through altering the mobile phase composition to influence the partition coefficient (k) or separation factor (α) in GC.

2.1 Selection of Gases

The choice of a practical carrier gas is simple: nitrogen or helium. Air may be used as a carrier gas under certain conditions with portable or on-site chromatographs but this is uncommon with laboratory-scale instruments. The choice of nitrogen or helium is made, in part, on the principles of separation and, in part, on economics: ~$20 for a nitrogen cylinder versus ~$50 for a helium cylinder. However, the selection is more complex than the prices of gas cylinders alone. Column efficiency in GC contains a term for contributions to longitudinal broadening in the carrier gas and this is given by the D_g term in the van Deemter equation.[3] This term is proportional to the square root of molar mass for the carrier gas, and nitrogen or argon would be preferred over helium based on D_g only. This effect can be seen in Figure 3, where nitrogen provides better performance than helium and has the lower contribution to plate height. However, the shape of the curve for height equivalent to a theoretical plate (HETP) versus flow rate (as linear velocity) for helium shows a reasonably good efficiency at high flow rates.[1,4] (HETP is equal to L/N, where L is the column length and N is the number of theoretical

Figure 3 Plot of separation efficiency versus column flow rate.

plates in a column.) In contrast, the van Deemter curve for nitrogen is comparatively narrow. Consequently, a GC separation using nitrogen at 10 cm s^{-1} can be accomplished with comparable separating efficiency using helium at 50–60 cm s^{-1}. The practical consequence of this is that costs for using helium, on a per sample basis, might be lower than those for nitrogen when the speed of analysis is factored into the calculations.

2.2 Control of Flow

One difficulty in GC is the compressibility of the carrier gas and subsequent influence on separating performance. This was recognized in the first paper on GC where correction factors for gas flow rates were described.[5] The implications for isothermal methods are significant but will be critical with temperature programmed GC when column temperatures may span 200 °C or more.[6,7] When temperature is increased for a column with constant pressure on the inlet, the average flow rate in the column will decrease owing to increased viscosity of the gas mobile phase in a proportional but nonlinear manner. Under such conditions, flow rates may slow at high temperature and both separation speed and efficiency may suffer. Flow may be kept constant through mass flow meters that have inlet and outlet orifices, adjustable based upon pressure differences.[2] Constant flow can be delivered across a range of pressure drops that may arise due to changes in temperature but cannot compensate for changes in barometric pressure. An advance in instrumentation during the past decade has been the commercialization of flow programming so that flows may be made highly reproducible.

2.3 Gas Sources and Purity

A common gas source for nitrogen or helium is the pressurized cylinder or bottled gas supply, readily supplied

as a steel tank with a two-stage pressure regulator. This is still a common gas source though gas generators for nitrogen (air and hydrogen too) can be commercially competitive with bottled gas and have advantages in safety.

Regardless of the gas source, special attention must be given to the purity of tubing used to connect the source and the gas chromatograph and to impurities in the gas supply. Most columns do not tolerate moisture and oxygen well when operated at temperatures over 100 °C. Best results for column longevity and chromatographic reproducibility occur when the carrier gas is cleaned over molecular sieve beds (to reduce moisture). In addition, specialized traps can be purchased to reduce or remove hydrocarbons and oxygen in the carrier gas.

3 SAMPLE INLETS

The chromatographic process begins when sample is introduced into the column, ideally without disrupting flows in the column. The chromatographic results will be reproducible inasmuch as this is accomplished with a minimum of change in pressure or flow of the carrier gas or mobile phase. Also, the injection step establishes the initial (and best possible) peak width for the GC measurement. Thus, delivery of sample into the column should be controlled, reproducible, and rapid.

3.1 Syringes and Switching Valves

A common method for placing samples on a GC column is to use the microliter syringe with a needle to penetrate a plastic membrane. In this method a gas-tight seal is maintained and sample is deposited into a heated zone. If liquid or solid, sample is volatilized and swept to the column and this can be accomplished by manual injections in ~1 s. Syringe injection is a convenient and generally effective method though the thermoplastic septum develops leaks after repeated injections. Fatigue of the plastic septum limits the number of injections to ~30 before the septum must be replaced. A second difficulty arises with impurities from off-gassing or decomposition of the septum and these are seen as so-called ghost peaks or peaks in control blanks.[8]

Advances with capillary columns introduced unprecedented precision and accuracy to GC measurements and limitations with syringes became apparent.[9] Discrimination toward high boiling point components was seen with syringe injections and techniques to remedy the failings have been developed.[9] Sometimes thermal volatilization may lead to decomposition of samples so efforts to remove the discrimination and decomposition motivated the use of so-called on-column injections where sample is deposited directly from the syringe into the column. Another complication with syringe injections is the introduction of particulate and reactive materials into columns. Protection is afforded by precolumns. Further information on syringe injections and the range of options for injection methods can be found in excellent reference sources.[10,11]

Gas samples can be injected into the column using gas-tight syringes or using rotary gas switching valves that offer enormous flexibility for GC instruments.[12] Precision gas switching valves allow a gas sample to be measured with a precise volume and introduced into carrier gas flow without interrupting column flow. Sample is loaded into a loop and then, with a change in the valve position, is swept into the column under flow of the gas source. Heated switching valves such as those made by VICI, Inc.[13] are also useful in the analysis of sorbent traps. When traps are heated and switched in-series with the analytical column, constituents will be thermally desorbed for GC separations. Switching valves can be automated via electronic actuators and can be incorporated into purge-and-trap methods that are useful for characterizing aqueous samples for volatile organic constituents.

3.2 Pyrolysis

Another inlet option which is now routine in certain specific applications of material sciences is that of sample pyrolysis where solid samples are rapidly heated to a point of thermal decomposition in a reproducible manner. At temperatures in excess of 600 °C, substances such as natural or synthetic polymers thermally decompose to small molecular weight, stable substances that provide a chromatographic profile which is unique to certain materials. Such an injector enlarges the application of GC to solid samples that would not normally be considered suitable for GC characterization, and pyrolysis methods have become standardized for some applications such as assaying plastics. A journal now exists for analytical applications of pyrolysis, the *Journal of Analytical and Applied Pyrolysis*. Attachments to inlets are commercially available and serve to extend GC in forensic and industrial applications, as shown in Table 1.

3.3 Other Topics

In purge-and-trap methods, a small amount of water is treated vigorously with an inert gas flow sufficient to sweep volatile organic compounds (VOCs) into the gas phase from the water phase. The gas flow, including the VOCs, is passed through an adsorbent trap where VOCs are retained and concentrated while water vapor and

gas are unretained and released to vent. After a short time of purging, the trap is placed in series with the gas chromatograph via a gas switching valve and VOCs are transferred to the analytical column. This is done through a rapid increase in temperature of the sorbent trap and the vapors are carried to the analytical column under carrier gas flow. Purge-and-trap methods are the basis for an expansive use of GC for monitoring the VOCs at ppb levels in aqueous samples as specified[21,22] by the United States Environmental Protection Agency (USEPA). Such instrumentation and methods are available today in commercial instrumentation and can be fully automated. An advantage in this method of sample preparation is that nonvolatile constituents, which could potentially foul the column, remain in the sample container and do not enter the column.

Another adaptation of GC for trace organic analysis was the development of solid-phase microextraction (SPME) with a syringe design. In this, a stationary phase is bonded on a silica fiber that can be introduced to a gas or aqueous sample. Organic chemicals partition into the coated fiber during a time of contact and the fiber is withdrawn into a syringe needle. In an injection port the fiber is pushed from the protection of the needle and sample is thermally desorbed into the GC column. This method has advantages of convenience and simplicity and the growth of use of SPME injections has been dramatic during the 1990s. A list of some representative applications is given in Table 2.

4 OVENS

4.1 Conventional Designs

Liquids or solids must be converted to vapor state and maintained as a vapor throughout the GC separation. Therefore, most gas chromatographs are equipped with ovens to keep the column at temperatures from 40 to 350 °C. Exceptions are those chromatographs that are used in separating simple gases such as light hydrocarbons or permanent gases. Early gas chromatographs were equipped with isothermal ovens. Today, temperature-programmed ovens allow separations of chemicals spanning a range of vapor pressures in a single analysis.

Conventional ovens, unchanged in decades, consist of a resistive wire coil that radiates into the inner volume of the oven. Heat from the resistive wire source is spread, ideally in an even manner, throughout the oven volume using a fan attached to an electric motor. A thermistor or thermocouple inside the oven is part of regulating the oven temperature via the amount of heat released by the heating element. This is controlled by the power delivered to the element and a feedback circuit to control and program the oven temperature. Efforts to create isothermal conditions, i.e. no thermal gradients inside the oven volume, are essential for reproducible chromatography and are criteria in evaluating good oven designs. Gradients in excess of a few degrees between various regions of an oven are practical in the best of oven designs and can be more than a few degrees in poorly designed ovens. One of the only systematic evaluations of GC ovens was given by Welsh[31] and his discussion provides measures for characterizing GC ovens.

4.2 Other Designs for Control of Column Temperature

Several alternatives to conventional ovens have been devised and may be especially helpful for short columns or instances where little space is available for a bulky, heated air oven. Two approaches have been used and include small thermal ovens[32] and innovative column heating arrangements.[33] Column heating based on resistive heating is compact, uses minimal power, and can decrease analysis times.[34] These methods are based upon application of heat directly to the column or a base upon which the column is crafted or attached. The approach is unlikely to become a laboratory standard but is being explored for use in miniature or portable gas chromatographs.[35]

5 DETECTORS AND DATA SYSTEMS

The subject of detectors in GC is a pivotal theme since the separation processes will have been wasted if the analyte

cannot be detected. Excellent primers on GC detectors are available[36,37] and any general text on instrumental analysis will have introductory material on the common detectors. A biennial review contains an extensive section on developments of GC detectors and can serve as a guide to primary literature.[38]

5.1 Detectors

Effluent from the column enters a detector where the composition of the carrier gas stream is characterized through one of several possible chemical or physical properties of molecules. The mainstays in GC have been the flame ionization detector (FID), the thermal conductivity detector (TCD) and the electron capture detector (ECD). Other commercially available detectors include the photoionization detector (PID), the nitrogen–phosphorus detector and the atomic emission detector, though these have been less prevalent historically than the FID, TCD, and ECD. Other detectors have been introduced through the years but have never become widely used in GC methods. The FID relies upon the formation of gaseous ions from organic molecules combusted in a hydrogen–air flame; the TCD is based upon changes in the heat absorbing properties of the gas effluent when the carrier gas is altered with analyte; the ECD response is governed by the ability of some molecules to attract and remove thermalized electrons. Despite long-standing conventions for the design and operation of these detectors, advances still occur.

Examples of evolutionary changes include the small FID designs[39] and designs where gas mixing is arranged to provide optimum response.[40–42] A recurring theme in advances in ECD has been a nonradioactive alternative to the normal source, 10 mCi of ^{63}Ni. Despite promising discoveries, the radioactive source is still the favored choice. The applications of ECD illustrate the advantages of selective detectors where analyte can be found in the presence of potentially interfering matrix.

Examples where the ECD was chosen to detect a specific chemical family over interfering backgrounds include: halocarbons in air for oceanographic tracer studies;[43] chlorobutanol in mouse tissues and fluids;[44] organochlorine compounds in milk products;[45] pesticides and other organochlorides in water;[46] organochlorine pesticides in edible oils and fats.[47]

In the last two decades, inexpensive mass spectrometers or mass-selective detectors (MSDs) have dramatically transformed the practice of GC. Once the purview of laboratories able to sustain the high cost of mass spectrometers and the high level of maintenance, instrument manufacturers made mass spectrometers both robust and inexpensive. This development, when combined with the appreciation that analytical confidence is highest with a mass spectrometer as the detector, has resulted in a near general availability of gas chromatography/mass spectrometry (GC/MS) instrumentation. In a GC/MS analysis, a mass spectrum can be obtained continuously at fixed intervals of ~0.1 s throughout the analysis. Consequently, a mass spectrum can be obtained for each chromatographic peak and the shoulders and baselines in the chromatogram. No other detector can provide the richness of information available in such results. Detection limits can be enhanced through the use of single ion monitoring where the mass spectrometer is used for detecting the intensity of one or a few ions. This can provide the specificity of a mass spectral pattern for response without losses in detection limit associated with scanning over unused m/z space. One revolution in the past decade has been the application of powerful desktop computers to control instrumentation and especially to control data acquisition and handling.

5.2 Data Systems

At a fundamental level, acquisition of chromatographic results has been little changed since the early days of GC, though the digital revolution has meant that strip chart recorders, once the mainstay of collecting chromatograms, cannot be found today and only electronic recording-integrators or microcomputers are used. Signal from the detector amplifier is digitized and stored to disk allowing enormous convenience in retrieving and replaying results. This means that peak retention times, peak areas, etc. are automatically reported and have been since the mid-1970s. In addition, software allows the results to be displayed in an automated manner, i.e. reports can be generated according to standard reporting formats. All this can be economically integrated into the total instrument control and management through computers and is an option on all chromatographs and a standard feature on most instruments.

6 MINIATURIZED, HIGH-SPEED, AND PORTABLE GAS CHROMATOGRAPHS

One area of GC that has shown vibrancy with advances during the 1990s is that of small, fast, and portable GC instruments. Though process gas chromatographs were amongst the first sophisticated analyzers placed into industrial on-site measurements, the subject has taken new significance following the burgeoning environmental movement. Making measurements where a sample is located rather than relocating samples to a centralized laboratory underlies this trend. Recently, a new journal

has appeared to support these efforts, *Field Analytical Chemistry and Technology*, which includes portable GC advances.

In high-speed GC, retention times can be pushed under a few minutes or seconds with short, narrow bore columns or high flow rates. Part of the challenge in fast GC is the compressibility of the carrier gas and the necessary speed (low time constants) for subcomponents such as injectors and detectors for high-speed separations.

6.1 Instrument Designs

An example of the size possible for small gas chromatographs is an ultimate miniature gas chromatograph created using silicon micromachining and integrated circuit processing techniques.[48] This GC analyzer contains a 0.9 m long × 300 μm wide × 10 μm high rectangular column coated with a 0.2-μm thick liquid phase. The injector is a 10-μm-long sampling loop with the same cross-section as the column. Dual detectors based upon a coated chemiresistor and on thermal conductivity are used. The complete system is packaged in less than 23 cm^2 and is 2.5 mm high. Although limited in scope to the detection of ammonia and nitrogen dioxide, this miniature chromatograph offers exciting possibilities for future field instruments.

One trade-off for high-speed GC is the loss of capacity due to the smaller diameter and shorter columns. Application of packed capillary columns in high-speed GC has been shown to improve capacity and selectivity[49] while obtaining high-speed separation for light hydrocarbons.[50] An alternative is the multicapillary column which improved capacity while maintaining the efficiency obtained with small internal diameter columns.[51]

Injection techniques for high-speed GC must provide narrow bandwidths due to fast analysis time requirements without compromises in resolution.[52] One means to accomplish this is through cryogenic inlets which provide narrow bandwidths[53] and in some instances injection times can be shorter than 10 ms.[54]

6.2 Detectors

Mass spectrometers might be considered ideal detectors and adaptations to fieldable gas chromatographs have been made. One design is the size of a standard size suitcase, weighs ~31 kg and uses ~600 W under peak loads.[55] Naturally, field portability is a goal and man-portability has been demonstrated.[56] A cart-portable unit has been described and was capable of screening 1000 samples an hour at a speed of 20–32 km an hour.[57] Portable GC/MS instruments were also used for industrial hygiene applications.[58] As the need for field measurements increases and mass spectrometry (MS) becomes miniaturized, the number of field portable GC/MS systems can be expected to increase dramatically.

Another sophisticated detector for GC is the ion mobility spectrometer and recently it too has been coupled to gas chromatographs for field analysis.[59,60] The utility of this hand-held gas chromatograph/ion mobility spectrometer analyzer was demonstrated by rapid screening (~20 s) with chemical warfare agents such as dimethyl methylphosphonate.[61] One of the most impressive demonstrations was that from the US Army where a portable pyrolysis-gas chromatograph/ion mobility spectrometer was developed for screening airborne pathogens. This unit is shown in Figure 4.

This part of GC instrumentation may be expected to undergo continued development as interest in speed of analysis pushes dimensions and hardware. Therefore, it represents one of the few areas of growth in GC

Figure 4 Gas chromatograph/ion mobility spectrometer for bacterial analysis.

instrumentation that can be recognized in the absence of a revolutionary change in GC methods.

In gas chromatography (GC) the liquid phase, also called the stationary phase, provides the medium in which the separation occurs. The magnitude of separation is given by the relative strengths of intermolecular interactions between analyte and stationary phase molecules, thus numerous liquids have been used over the years. The stationary phase can be coated onto a solid support and packed into a tube (packed column GC), or coated onto the wall of a capillary (capillary GC). Today, most GC analyses are performed using capillary columns.

1 INTRODUCTION

In GC, the liquid phase, which is coated onto the inside wall of a capillary column, or onto solid particles in a packed column, is commonly referred to as the "heart" of the system, as this is where the entire separation occurs. Since the inception of GC, the design of columns and of liquid phases has undergone significant changes, but columns may still be classified into several distinct categories. If the stationary phase is a solid, the technique is termed gas–solid chromatography (GSC); if it is a liquid, then the technique is called gas–liquid chromatography (GLC). Packed columns arise from packing a tube, typically 6.3 or 3.2 mm (1/4 or 1/8 inch) in outside diameter with stationary phase particles that may or may not be coated with a liquid phase. Capillary or open tubular columns come in a variety of dimensions, from 0.05 mm to 0.53 mm in inside diameter and have a liquid or solid stationary phase coated onto the inside walls of the capillary. Capillary columns are generally used for applications that demand high resolution, trace analysis or high temperatures, while packed columns are generally used for applications requiring high sample capacity, ease of use and low temperatures. This article addresses liquid phase coatings for packed and capillary columns.

In any GC column, packed or capillary, the ability to achieve a separation depends upon specific interactions between the stationary phase material and the specific analytes, and upon the vapor pressure of the analyte. As a rule of thumb, GC can analyze any compound for which vapor pressure or boiling point data can be obtained by other methods. The specific interactions include dispersion forces, hydrogen bonding and weak electrostatic interactions. It is the need to modulate these interactions to produce a desired selectivity and the need for stable inert liquid phase materials that drives the development of new stationary phases. Column dimensions, such as length, tubing inside diameter, liquid phase loading and particle diameter for packed columns and length, tubing inside diameter, and liquid coating film thickness for capillary columns also have strong effects on separation capability.

Table 1 Time line of important developments in liquid phases for GC

Date	Event
1952	GC invented by Martin and James; Packed columns developed
1958	Theory of capillary column performance described
1958	RI proposed
1959	Patent on capillary columns by Perkin Elmer; inlet splitter
1960	Glass drawing machine developed by Desty
1966	Rohrschneider introduces phase constants
1979	Fused silica capillary columns invented
1983	Introduction of megabore columns as alternative to packed columns
1980s	Development of quality testing and deactivation procedures; cross-linked polymeric phases; interface to spectroscopic detectors
1990s	Programmed temperature vaporizer; electronic pressure control

RI, kovats retention index.

Packed columns were introduced in 1952 by Martin and James along with the first gas chromatograph.[1] The vast majority of GC work in the 1950s–1970s was performed using packed columns, as capillary columns were prohibitively difficult to use for routine work at the time. Since the plate numbers of packed columns are limited, separation power was generated by novel stationary phase design, leading to the availability of hundreds of stationary phases and column designs. Today, use of packed columns is more limited, as capillary columns, with their high plate numbers and improved analytical sensitivity, have become routine.

Capillary, or open tubular columns, introduced in the late 1950s, were originally made of glass or stainless steel and were very difficult to use. In 1956, Golay[2] described the tremendous potential benefit of the open tubular arrangement. However, capillary columns saw relatively little routine use over the next 25 years, as the glass columns commonly in use were very difficult to make, install into instruments and easy to break. In 1979, Dandeneau and colleagues invented the fused silica capillary columns in use today.[3] Since then, capillary column manufacture and use has increased dramatically, capturing approximately 80% of the GC column market.[4] Immediate benefits were seen, as routine high-resolution trace analysis became possible. Table 1 provides a brief time line of major developments in GC liquid phase technology.

2 THE ROLE OF THE STATIONARY PHASE

In contrast to liquid phase chromatographic separations, in which separating power is determined by both the mobile and stationary phases, in GC, only the stationary phase–analyte interactions determine the separation capability of a column. The mobile phase (carrier gas) acts only as a carrier of vapor phase molecules. Thus, in developing GC methods, the nature of the stationary phase is a primary consideration. Both the chemical nature of the liquid phase and the dimensions of the column make strong contributions to the capability to develop a separation. Because the mass of liquid phase present in a capillary column is about 1000 times less than in a packed column, and because packed columns are practically limited to about 0.3 m (12 feet) in length, while capillary columns may be 100 m long or more, there are significant differences in approach to method development, so these are treated separately. These dimensional differences lead to the many different types of separations that can be performed on capillary columns.

2.1 Solute–Stationary Phase Interactions

Analyte vapor pressure and the nonbonded chemical interactions that influence solubility are the chief contributors to retention in GC. Thus, if high selectivity is the goal of choosing a stationary phase, these must be considered carefully. The major forces involved in determining the strength of retention on a given column are:

- London forces, which are based on dispersion between molecules and generate the effective boiling point of the analyte sorbed onto the stationary phase;
- Keesom forces, which are dipole–dipole interactions between analyte and stationary phase molecules;
- Debye forces, which are induced dipole-induced dipole interactions between analyte and stationary phase molecules; and hydrogen bonding in which polar functional groups on the analyte molecules interact with similar groups on the stationary phase.

Of these, hydrogen bonding and London forces will provide the strongest interactions, while Keesom and Debye forces will be secondary. Thus, in choosing a stationary phase, structural similarity between the analyte and stationary phase, which for nonpolar compounds results in London forces and for polar compounds results in hydrogen bonding, should be the major consideration in determining the retention power of the stationary phase for a given analyte, or the selectivity for a given group of analytes.

The basic characteristics required of all GC stationary phases can therefore be summarized. First, the analyte must be soluble in the stationary phase material. In selecting a phase, ''like dissolves like'' is often sufficient for effective choices. Otherwise, considering hydrogen

bonding and other intermolecular interactions between analyte and stationary phase is required. Second, if more than one component is present in the mixture, the differential solubility, which determines selectivity, of the analytes in the stationary phase must be high. Physically, the stationary phase should exhibit low vapor pressure, so that it can be operated at high temperatures and should have low viscosity at lower temperatures. These variables will be addressed further in sections 3.5 and 4.3, for packed and capillary columns, respectively.

In the 1960s, much work focused on the characterization of the many stationary phases then available for packed columns. The classic work performed by Kovats, Rohrschneider and McReynolds provided much of the basis for future developments in column chemistry. Also, in the 1970s and 1980s, quality tests developed by Grob, Grob and Grob[5,6] and others, continued to provide insight into column chemistry and performance. The Grob tests are addressed further in section 5.3. In order to compare chemistry among diverse stationary phases, a common means for recording retention times that accounted for variations on operating conditions was required. The Kovats retention index (RI)[7] was the first of these. Retention times of the *n*-alkanes are used as standards and the retention times of other compounds are calculated by Equation (1):

$$\mathrm{RI} = 100N + 100 \ \frac{\log t'_{\mathrm{R}}(\mathrm{an}) - \log t'_{\mathrm{R}}(N)}{\log t'_{\mathrm{R}}(N+1) - \log t'_{\mathrm{R}}(N)} \qquad (1)$$

where RI refers to the retention index of compound "an", N refers to the number of carbon atoms in the normal alkane eluting immediately before the analyte and $N+1$ refers to the normal alkane eluting immediately after the analyte; t'_{R} refers to the adjusted retention time. This was modified for linear temperature programs (Equation 2):

$$\mathrm{RI} = 100N + 100 \ \frac{t_{\mathrm{R}}(\mathrm{an}) - t_{\mathrm{R}}(N)}{t_{\mathrm{R}}(N+1) - t_{\mathrm{R}}(N)} \qquad (2)$$

This form of relative retention calculation results in a retention index that allows retention to be reported free of minor instrumental variations and variation in column dimensions. The Kovats indices also provide retention values that are directly proportional with the free energy of the bulk solute–stationary interactions. Thus, direct retention comparisons can be made between columns with differing dimensions and liquid phases. Tables of retention indexes have been published.[8] Several other authors[9–12] have developed alternative retention index systems, but the Kovats system remains most widely used.

Using the retention indexes of selected compounds (test probes) Rohrschneider[13] and McReynolds[14] developed schemes for assessing the chemical characteristics of GC stationary phases. A summary of the test probes used by McReynolds and Rohrschneider is shown in Table 2, along with the chemistry being measured by each test probe. Both McReynolds and Rohrschneider chose squalane, the liver oil of sharks, a nonpolar mixture of long chain, highly branched hydrocarbons, and one of the classical GC liquid phases, as a standard liquid phase. First, they measured the RI of each test probe on squalane. Next, for other phases, they measured the RI under identical conditions. The McReynolds constant for the new phase is given by the difference in RI for the test probe on the new phase versus squalane. For example, a high McReynolds constant for benzene indicates a column that will strongly retain compounds that are likely to undergo induced dipole interactions, such as other aromatics and olefins. Table 3 shows McReynolds constants for some common stationary phases. Today, column vendors and others who report stationary phase characterization data still report Rohrschneider–McReynolds constants.[15] The structures and chemistries of these stationary phases are defined in more detail in sections 3.6 for packed columns and 4.4 for capillary columns.

Table 2 Summary of phase constants used by McReynolds (M) and Rohrschneider (R)

Compound	Purpose
Benzene (M, R)	Measures induced dipole attraction (aromatics and olefins)
n-Butanol (M, R)	Measures electron attracting groups (alcohols, nitriles, acids, halogens)
2-Pentanone (M, R)	Measures electron repelling groups (ketones, ethers, aldehydes, esters)
Nitropropane (M, R)	Measures ability to form complexes
Pyridine (M, R)	Measures ability to form complexes
2-Methyl-2-pentanol (M)	Substituted alcohol – interactions similar to *n*-butanol
Iodobutane (M)	Polar alkane interactions
2-Octyne (M)	Unsaturated hydrocarbon interaction similar to benzene
1,4-Dioxane (M)	Proton acceptor
Cis-hydrindane (M)	Dispersion

2.2 Important Separation Variables

As can be noted from the above discussion of McReynolds constants, there are many variables related to retention and flow in columns that are important in any discussion of stationary phase characteristics. Thermodynamics of the phase transfer between mobile and stationary phases mostly determines the retention time of any analyte. This is most easily expressed as the standard free energy change, ΔG° of the partitioning process between the mobile and stationary phases. The partition coefficient,

Table 3 McReynolds constants for common stationary phases. (Reprinted with permission from H. McNair and J. Miller, *Basic Gas Chromatography*, New York, John Wiley and Sons, 1998, 64.)

Liquid phase	Benzene	*n*-butanol	2-pentanone	Nitropropane	Pyridine

OV-275	629	872	763	1106	849

DEGS, diethyl glycol succinate.

K_p is given by Equation (3):

$$K_p = e^{-\Delta G^\circ/RT} \tag{3}$$

Which leads to the retention factor (Equation 4):

$$k = \frac{K}{\beta} \tag{4}$$

And to the retention time (Equation 5):

$$t_R = t_m(1 + k) \tag{5}$$

The value of the standard free energy is given by the specific stationary phase–analyte combination. This derivation is reviewed in more detail by Snow[16] and forms the basis for the many efforts to predict retention times from thermodynamic data.[17–19] These thermodynamic arguments are the same for both packed and capillary columns, with the major difference being that phase ratios (β), the ratio of gas phase volume to liquid phase volume within the column, for capillary columns are generally 1–2 orders of magnitude larger then for packed columns.

Not only does the identity of the stationary phase determine the retention time, but the dimensions of the column have a profound effect on the retention time and the peak width, and ultimately the chromatographic resolution of closely eluting peaks. A summary of the important variables and their effects is given in Table 4. The master resolution Equation (6), as described by Purnell[20] also provides a useful summary, as high resolution is the goal of most chromatographic method development.

$$R_s = \left(\frac{k}{1+k}\right)\left(\frac{\alpha-1}{\alpha}\right)\left(\frac{\sqrt{N}}{4}\right) \tag{6}$$

Terms relating to retention $k/(1 + k)$, selectivity $(\alpha - 1/\alpha)$ and system efficiency $(\sqrt{N}/4)$ are seen to each contribute to the overall resolution. Two peaks with $R_s = 1.5$ are said to be ''baseline resolved''. According to this equation, for the largest resolution to be achieved in the shortest time, k, which is highly temperature dependent, should vary in the relatively tight range of 2–20, with little return seen in raising k above 20. N and α will vary greatly according to the column type, dimensions and stationary phase. Using the master resolution equation, van Deemter and Golay equations, packed and capillary columns can be examined separately and compared.

Table 4 Summary of important column-related variables and their effects on GC retention times and peak widths

Variable	Effect on retention	Effect on peak width
Column length	Retention times longer; peaks are separated further	Peaks broaden with length, but N higher
Column internal diameter	None if linear gas velocity the same	Narrower column; sharper peaks
Particle diameter (packed columns)	Pressure drop increased with smaller particles; retention time longer at same inlet pressure	Smaller particles; sharper peaks
Liquid phase film thickness	Thicker film; longer retention	Thinner film; sharper peaks
Column temperature	Increased temperature; decreased retention time	Increased temperature; sharper peaks; effect on N difficult to define; check maximum and minimum temperature before using column

2.3 Packed Columns

As discussed in section 3 of this chapter, the length of a packed column is limited by the inlet pressure that can be practically be generated by the gas chromatograph, leaving typical lengths in the 6–12 foot range. Limiting the column length also limits the number of theoretical plates, with typical values for a 6.3 mm (1/4 inch) outside-diameter column being 6000–10 000 theoretical plates. The master resolution equation (Equation 6) can be used to describe the requirements for a column. If a desired resolution of 1.5 is assumed and that "normal" chromatographic conditions include k from 1–20 and N from 1000 to 10 000, the selectivity required to achieve a resolution of 1.5 is easily calculated by rearranging the master resolution equation. Table 5 shows the results of such a calculation using the master resolution equation, solved for selectivity. It is seen that selectivity greater than 1.064 is needed to achieve baseline resolution in the best case for packed columns, while for most packed columns, the necessary selectivity is higher. Since selectivity in GC is entirely based upon the nature of the solute–stationary phase interactions, the choice of liquid phase is critical in the development of nearly every method. This has led to the development of a very wide variety of liquid phases for packed columns, which are treated in more detail in sections 3.5 and 3.6.

Peak widths in packed columns are related to the height equivalent to a theoretical plate (HETP or H), which is described by the van Deemter equation (Equation 7):[21]

$$H = 2\lambda d_p + \frac{2\gamma D_M}{\mu} + \frac{qkd_f^2\mu}{(k+1)^2 D_s} \qquad (7)$$

The variables are described in the list of symbols at the end of this article. Many of the terms in this equation are related to the nature and dimensions of the liquid phase. The diameter of the stationary phase particles affects eddy diffusion in the first term, with larger particles generating larger H. Mass transfer in the stationary phase is affected by the diffusivity of the solute, indicating that less viscous liquid phases will provide lower H, as will a thinner film of liquid (smaller loading). The film thickness has the most dramatic effect, as it is squared.

Table 5 Selectivity requirements for packed and capillary GC columns, calculated from the master resolution equation

k	1000	2000	5000	10 000	50 000	100 000	250 000
1	1.612	1.367	1.204	1.136	1.057	1.039	1.025
2	1.398	1.252	1.146	1.079	1.042	1.029	1.018
5	1.295	1.192	1.113	1.078	1.033	1.023	1.015
10	1.263	1.137	1.103	1.071	1.030	1.021	1.013
15	1.254	1.132	1.100	1.068	1.029	1.021	1.013
20	1.250	1.130	1.098	1.067	1.029	1.020	1.013
∞	1.234	1.154	1.093	1.064	1.027	1.019	1.012

2.4 Capillary Columns

Due to their length (10–100 m), capillary columns have much higher plate numbers than packed columns. In terms of generating resolution, therefore, the necessary selectivity for capillary columns is significantly less than for packed columns. Table 5, above, also shows the calculation of the necessary selectivity required to achieve a resolution of 1.5, for capillary columns, assuming retention factors between 1 and 20 and plate numbers between 10 000 and 500 000, typical values for capillary columns. It is seen that lower selectivity values, 1.012 (compared with 1.064 for the packed column described above) for $k = 20$ and $N = 250\,000$, are needed than for packed columns. Thus, in the initial developments, there were far fewer liquid phases available for capillary columns than for packed columns, as stationary phase selectivity is less critical in the achievement of separation.

The Golay equation[2] (Equation 8) can be used to describe HETP for capillary columns.

$$H = 2D_M\mu + \frac{1 + 6k + 11k^2}{24(1+k)^2}\frac{r_c^2}{D_M} + \frac{2kd_f 2\mu}{3(1+k)^2 D_s} \qquad (8)$$

It differs from the van Deemter equation in that, since a capillary column is an open tube, there is no term for eddy diffusion and since there is a much greater relative amount of mobile phase in a capillary, there is an additional mass transfer term for the mobile phase. The major variables that are affected by the liquid phase are the diffusivity of the solute in the liquid phase, indicating that low viscosity liquid phases are desirable, as are thin films. Again, the film thickness has the most dramatic liquid phase-related effect on H and therefore, on the peak width.

2.5 Comparison of Packed and Capillary Column Separations

Chromatograms showing packed and capillary column separations of a polychlorinated biphenyl standard that demonstrate the characteristics of each resulting from the above theory are shown in Figures 1 and 2.[22] About 15 peaks are shown in the packed column separation, which demonstrates about 1500 theoretical plates. The capillary column separation shows about 60 peaks and about 100 000 theoretical plates. Both separations were conducted isothermally, with the same liquid phase. Thus, with the same selectivity, the capillary column provides sharper peaks with much greater resolution in a similar analysis time. The greater mass of stationary phase in the packed column also requires higher elution temperatures and a slower analysis time, with much greater consumption of carrier gas and lower sensitivity.

The selectivity factors, as described above and calculated in Table 5 have a dramatic effect on the separation power of a column. For example, if $k = 5$ and

Figure 1 Packed column GC separation of a polychlorinated biphenyl standard Arochlor® 1260; isothermal at 210 °C; 1500 theoretical plates. (Reprinted with permission from H. McNair and J. Miller, *Basic Gas Chromatography*, New York, John Wiley and Sons, 1998, 94.)

Figure 2 Capillary column GC separation of a polychlorinated biphenyl standard Arochlor® 1260; split 30 to 1; isothermal at 210 °C. (Reprinted with permission from H. McNair and J. Miller, *Basic Gas Chromatography*, New York, John Wiley and Sons, 1998, 94.)

$t_R = 10.0$ min is assumed for a typical peak, then the next eluting peak must have a retention time of at least 10.616 min for baseline resolution to be achieved on a packed column having 10 000 theoretical plates. For a capillary column having 250 000 theoretical plates, under the same conditions, the required retention time for the next peak is 10.120 min. This indicates that the capillary column can separate much more complex mixtures than a packed column, as many more peaks can fit within the separation time, for example 20 min. Peak capacity of columns is described in more detail by Giddings.[23]

3 PACKED COLUMNS

Most of the early work in GC was performed on packed columns. Following the invention of the capillary column, they proved difficult to make and use, so work in GC continued with packed columns. Today, about 80% of all work in GC is done with capillary columns;[4] however, packed columns are still the method of choice for those analyses requiring the relatively large volume of liquid phase present in packed columns, such as fixed gases, solvents and other analyses in which partition coefficients are low, yet strong retention is required.

3.1 Tubing Materials and Dimensions

Typically, packed columns are 6.3 or 3.2 mm (1/4 or 1/8 inch) in outside diameter and 0.6–3.6 m (2–12 feet) long. Glass and stainless steel are the most common tubing materials, although nickel, Teflon®, copper, Teflon®-lined stainless steel and aluminum are also used. Copper and aluminum columns can be easily made in the laboratory from straight tubes, which can be bent to fit the instrument configuration, while the other materials must be purchased in the correct configuration for the instrument into which they will be installed. Figure 3 provides a summary of some common configurations used by major instrument manufacturers.

3.2 Solid Supports

In a packed column, the liquid phase must be coated onto a solid support material. Ideally, the support material should be capable of withstanding the physical stresses in GC, including high temperatures (up to 350 °C, generally) and moderate pressures (up to 5 atm), should be inert and not react with sample components or liquid phase materials and should be readily available in a variety of mesh sizes. The important physical properties include particle size, porosity, surface area and packing density. Smaller particles will provide more plates, as shown by the van Deemter equation, yet will require a higher

Figure 3 Packed column tubing configurations (a) Hewlett Packard 5890, 5880, 6890; (b) Perkin Elmer 8300, 8400, 8500, 8600, 8700, auto system; (c) Shimadzu GC14A, GC15A, GC16A; (d) Varian 3300, 3400, 3700, Vista Series.

pressure drop, necessitating a shorter column. A larger surface area, which is determined by the porosity, will require more liquid phase to achieve a complete coating. Diatomite supports, graphitized carbon blacks and, to a lesser extent, Teflon® are commonly used. Each of these has advantages and limitations, which are governed by their physical properties and by their surface chemistry.

Diatomite supports are all derived from the various forms of diatomaceous earth. Firebrick supports are obtained by heating, grinding and pulverizing bricks; filter aid supports are obtained by adding sodium carbonate to diatomaceous earth and heating to obtain an aggregate that is generally more inert than firebrick; and Chromosorb G is a filter aid support that has been additionally heat treated to generate more durable particles. Each of these may be further treated with a silylating reagent such as dichlorodimethyl silane (DMDCS), to cover active silanol functionalities on the surface, or may be acid or base washed to remove any active metal contaminants. It should be noted that silanized supports are very sensitive to hydrolysis by water, so care should be taken to eliminate water from any methods where they are used. Acid or base washing is used to eliminate reactive metals such as iron from the surface. These can act as Lewis acids and participate in the decomposition of liquid phases and analytes. Table 6[24] provides a reference to the common solid supports used for GLC.

The firebrick supports Chromosorb P and Gas Chrom R are pink in color and are very strong particulates, with dimensions as shown in Table 6. These have very high surface area and can accommodate liquid phase loading of up to 30%. As their surfaces contain active silanols, they are typically reserved for the analysis of nonpolar analytes, although they can be deactivated for analysis of polar compounds. The white calcinated supports, Chromosorb W, Gas Chrom Q and Suplecoport, for example, are preferred for polar analytes, although they are more fragile and accept slightly lower liquid loading (ca. 25%). Chromosorb G is denser and more durable than Chromosorb W, but can only accept about 5% loading of liquid phase.

Other materials, such as carbon black and Teflon® have been used as solid supports for gas liquid chromatography. Teflon® is typically used for the analysis of small polar molecules, such as water, acids, amines, alcohols, and other compounds that may be corrosive to diatomite supports. Teflon® has a relatively low upper temperature limit of about 250 °C and may develop static charges, making packing difficult. Carbon black is used as both an adsorbent and as a solid support. As a solid support, it allows for a combination of separation due to the liquid phase and the surface properties of the support, which separate according to the size and shape of the molecule. These are typically used for difficult separations of small molecules.

3.3 Packing and Preparing Packed Columns

Packed columns may either be purchased pre-made from a vendor, or they may be prepared in the laboratory from the appropriate length and diameter of tubing and the bulk packing material. Most common liquid phases are available precoated onto the solid support. When coating a liquid phase onto a solid support, first, the appropriate mass must be determined from the desired loading. There are three common methods for coating liquid phases onto solid supports:

1. Rotating Evaporator Method. The appropriate mass of liquid phase is dissolved in a suitable solvent in a round-bottomed flask and the weighed solid support is added. The solvent is then evaporated by rotary evaporation at reduced pressure.
2. Pan Coating Method. The liquid phase is dissolved in just enough solvent to wet the solid support and the

Table 6 Characteristics of selected solid supports for packed column GLC. (Reprinted with permission from E. Barry, *Modern Practice of Gas Chromatography*, ed. R. Grob, 2nd edition, New York, John Wiley and Sons, 131, 1995.)

Source	Support	Packing density ($g\,mL^{-1}$)	Surface area ($m^2\,g^{-1}$)	Pore volume ($mL\,g^{-1}$)	Maximum liquid phase loading (%)
Firebrick	Chromosorb P, NAW, AW/DMDCS, AW	0.32–0.38	4–6	1.60	30
Celite Filter Aid	Chromosorb W AW	0.21–0.27	1.0–3.5	3.56	15
Celite Filter Aid	Chromosorb W HP	0.23	0.6–1.3	3.56	15
Celite Filter Aid	Chromosorb G NAW, AW/DMDCS, HP	0.49	0.5, 0.4(HP)	0.92	5

AW, acid washed; NAW, not acid washed.

solution is added to the solid in a pan. The solvent is allowed to evaporate with gentle agitation and heat.

3. Funnel Coating Method. 20 g of solid support is added to 100 mL of liquid phase solution in a filter flask. The flask is placed under vacuum for a few minutes. The pressure is released and the mixture is placed in a sintered glass funnel and vacuum is applied for several minutes. The resulting solid is allowed to air dry.

More details on the coating of solid supports can be found in Barry.[24]

Glass and stainless steel tubing comes pre-shaped to fit into the instrument's fittings; copper and aluminum tubing can be bent into the appropriate shape. The pre-shaped tubing is available for a wide variety of vendors' instruments and column lengths. To pack the stationary phase into a 6.3 or 3.2 mm (1/4 or 1/8 inch) outside-diameter tube, a funnel, with a short piece of Tygon® tubing, a small amount of glass wool and an electric engraving tool are needed. Plug one end of the tubing loosely with glass wool, and using the funnel, connected to the other end by the Tygon® tubing, add the stationary phase. Vibrate the tubing and add stationary phase until no more can be added. Plug the open end of the column with a small piece of glass wool, leaving the appropriate length for the GC inlet and syringe needle unpacked. Following packing, the column should be installed into the instrument, carrier gas flow established and should be conditioned for several hours at a temperature 25 °C above the maximum temperature at which it will be used, but below the maximum temperature of the liquid phase.

3.4 Instrumentation Requirements

There are several instrumental considerations in the use of packed columns. First, the flow systems, inlets and detectors should be able to accommodate high carrier gas flow of 50–100 mL min^{-1}. On-column, direct, or gas valve injection are most commonly performed on packed columns, as syringe needles will easily fit within 6.3 or 3.2 mm (1/4 or 1/8 inch) tubing, and valve pneumatics are easily connected. This does provide the advantage of quantitative sample transfer into the column, without the use of splitters or special syringes, which are required for capillary columns. Packed columns have high thermal mass, requiring a very powerful oven heater and cooler if temperature programming is desired. This high thermal mass makes isothermal operation most common with packed columns. Due to the high flow rates, detector cells also are large and have high thermal mass, to maintain temperature equilibrium. In packed column gas chromatography/mass spectrometry (GC/MS), splitting devices must be used between the column and the detector, in order to reduce the flow entering the mass spectrometer sufficiently. Instrumentation for packed column GC is described in detail in **Instrumentation of Gas Chromatography** and in McNair[25] and Miller.[26]

3.5 Choosing a Stationary Phase

As shown in section 2 of this article, the relatively low plate counts of packed columns make the choice of liquid phase critical in packed column gas liquid chromatography. As a result, hundreds of liquid phases have been used over the years. A 1968 survey[27] indicated 179 commonly used liquid phases. A 1997 vendor catalog[28] lists 138, so a dizzying array of stationary phases remains available. Practically, it is not advisable to attempt to choose between all of these liquid phases; it is desirable to have a few choices that will solve most separation problems. The old maxim ''like dissolves like'' can provide a good start, as, from the discussion of stationary phase characterization presented above, it is difficult to develop a systematic scheme for choosing packed column liquid phases. Consulting the literature or the vendors' application notes is also a good place to start. Recently, Supelco has made a compendium containing over 200 of the packed column separations available.[29]

If consulting the literature does not provide a reasonable choice, then the McReynolds constants provide a starting point, as they measure the likely selectivity of the liquid phase for compounds similar to the test probes. For example, a liquid phase with a high value for the constant for *n*-butanol, would be a good choice for separating alcohols or other compounds expected to undergo hydrogen bonding. McNair and Miller[30] have provided a general summary of recommended stationary phases compiled by several workers, which is shown in Table 7. It is seen that these cover a wide range of polarities, and with appropriate temperature control, can achieve most separations. A nonpolar column is always included, as are several of moderate polarity, along with a highly polar silicone and

Stationary phase	Temperature range	Application
100% methyl polysiloxane	−60 °C to 350 °C	Alkaloids, amines, drugs, FAME, hydrocarbons, petroleum products, phenols, solvents, waxes, general purposes
5% phenyl–95% dimethyl polysiloxane	−60 °C to 350 °C	Alcohols, alkaloids, aromatic hydrocarbons, flavors, fuels, halogenates, herbicides, pesticides, petroleum products, solvents, waxes, general purposes
50% phenyl–50% methyl polysiloxane	−60 °C to 350 °C	Alcohols, drugs, herbicides, pesticides, phenols, steroids, sugars
14% cyanopropylmethyl–86% dimethyl polysiloxane	0 °C to 250 °C	Alcohols, arochlors, alcohol acetates, drugs fragrances, pesticides
50% cyanopropylmethyl–50% phenyl polysiloxane	0 °C to 250 °C	Carbohydrates, FAME
Trifluoropropyl polysiloxane	0 °C to 275 °C	Drugs, environmental samples, ketones, nitro-aromatics
Polyethylene glycol	60 °C to 225 °C	Alcohols, flavors, fragrances, FAME, amines, acids

FAME, fatty acid methyl esters.

a polyglycol. Structures 1–8 show the following liquid phases: 100% polydimethyl siloxane **(1)**; 5% phenyl, 95% polydimethyl siloxane **(2)**; 50% phenyl, 50% polydimethyl siloxane **(3)**; 100% cyanopropyl polysiloxane **(4)**; 6% cyanopropyl, 94% dimethyl polysiloxane **(5)**; 50% cyanopropyl, 50% dimethyl polysiloxane **(6)**; polyethylene glycol **(7)**; diethyl glycol succinate (DEGS) **(8)**.

Finally, once a potential liquid phase is chosen, the upper and lower temperature limits must be considered. At the upper temperature, the stationary phase itself has significant vapor pressure and will bleed from the column, reducing efficiency and shortening column lifetime. At the lower temperature, which may be the freezing point or glass transition temperature of the polymer, separation is also lost, as analytes no longer penetrate into the solid stationary phase.

3.6 Guide to Packed Column Gas Chromatography Liquid Phases

A few of the most commonly used packed column stationary phases are described above. There are, however, myriad stationary phases available. Table 8,[24] while not all-inclusive, provides a more extensive listing of common stationary phase materials and applications.

4 CAPILLARY COLUMNS

Capillary columns were first developed by Golay in 1957,[2] shortly after the initial development of GC. Theory predicts that the narrow, open-tubular format should provide very efficient transport of analyte molecules along the column length, and therefore, very sharp peaks. The initial glass capillary columns saw little routine use, however, as the glass columns had to be hand-drawn from larger tubing using an expensive drawing apparatus, and once made, were very fragile. In order to install a typical, helical glass column into an instrument, the glass first had to be straightened by heating, so that the appropriate compression fittings could be installed. Capillary GC has flourished since the development of the fused silica capillary column by Dandeneau and colleagues in 1979.[3] This development provided capillary columns that were

easy to handle and use. Other materials, such as stainless steel, aluminum cladded fused silica and Teflon® have also been used to make capillary columns for specific applications. The specific properties of these columns, as they relate to the liquid phase contained within them and to the development of separations, are discussed below. This section will also address the selection of appropriate capillary columns and stationary phases, along with a guide to stationary phase selection.

4.1 Design and Manufacture

Fused silica capillary columns are manufactured using optical capillaries with internal diameters commonly ranging from 0.100 mm to 0.530 mm, and with column lengths from 10–100 m. Smaller internal diameters are used for a few high-speed applications. The tubing is usually prepared by drawing a long length (hundreds of meters) using a drawing machine, which is then cut to the desired length after coating with the stationary phase. The fused silica tubing is coated on the outside with polyimide that provides flexibility and tensile strength, along with the characteristic brown color. Users of capillary columns should be warned to wear safety glasses at all times when handling columns that are coiled, as the coils can unwind with such force that a column end can damage the eyes. Fused silica capillary tubing is prepared by extruding larger diameter tubing in a furnace, with the drawing process controlled by an infared laser beam. Following drawing, the tubing is coated with a polyimide that provides flexibility, protection against water degradation and corrosion. The polyimide coating is stable to approximately 400 °C. For applications requiring temperatures higher than 400 °C, aluminum clad columns, in which the outer polyimide coating is replaced with a thin (ca. 20 μm) coating of aluminum can be used. These are commonly used in the separations of waxes, oils and triglycerides. Stainless steel has also been used as an outer coating for high-temperature work. The main advantage of stainless steel coating is that the column can be coiled very tightly, allowing it to be used in a small space.

Once the capillary tubing has been manufactured, it must then be prepared for coating, and coated with a thin (0.1–5 micron) film of liquid phase. The main requirements are the same as for packed columns: the column wall should be inert to the analytes and should allow the liquid phase to coat evenly. Classical coating techniques have involved the simple coating of polymeric liquids to the inside walls of the capillaries. More recently, the polymer has been chemically bound to the capillary wall. Prior to coating, the fused silica tubing must be deactivated, typically by reaction with silylating reagents. In 1985, Blomberg and Markides[34] presented a thorough discussion of organo-silicon chemistry for capillary columns, including a discussion of pretreatments. The techniques include D4-deactivation, in which the capillary is coated with octamethylcyclotetrasiloxane (D4), sealed and heated to 400 °C,[35] and the capillary heating with an appropriate polysiloxane,[36] high temperature silylation using hexamethyl disiloxane (HMDS),[37] and reaction with disiloxanes.[38]

Once the capillary inside surface has been deactivated, it must then be coated with the liquid phase polymer. A stable, thin (0.1–5 micron) and uniform coating is needed. Coating procedures were reviewed by Jennings,[39] with the most common method being static coating. In static coating, first described by Bouche and Verzele,[40] a solution of known concentration of the liquid phase is prepared in a volatile solvent. One end of the column is sealed and a vacuum is applied to the other end. Evaporation of the solvent leads to the deposition of a uniform coating of the less volatile liquid phase on the column wall. This method allows an accurate determination of the volume of stationary phase added to the column, and therefore the film thickness. Newly prepared capillary columns are then coiled into a circular metal cage to protect the column and to simplify mounting into the instrument oven. The chromatographic performance of a newly produced column can be evaluated using a column test mixture, as described later in this article.

4.2 Instrumentation Requirements

The specifics of GC instrumentation are discussed elsewhere in this Encyclopedia, however, there are several considerations that are directly related to the low carrier gas flow rates, small quantity of stationary phase, and open tubular nature of capillary columns. First, as shown by the Golay equation, the carrier gas flow rate is critical to the optimum performance of capillary columns, and should be adjusted carefully. Second, the small quantity of stationary phase, requires that analyte mass also be small, typically of the order of nanograms–picograms. Higher analyte quantities can overload the stationary phase, causing multiple retention mechanisms and distorted peaks. The open tubular nature of capillary columns indicates that the inlet–outlet pressure drop will be significantly less than for a packed column of the same length, allowing for very long (100 m is common) columns and high plate numbers. Column oven temperature control is also critical to optimum performance, as capillary columns, due to their low thermal mass compared to packed columns, are much more easily and rapidly temperature programmed. Thus the column oven itself should be of low thermal mass and be thermally insulated from other heated portions of the instrument. Most modern GC

ovens employ forced air convection for rapid heating and cooling of the capillary column. More details on instrumentation for capillary columns are provided in **Instrumentation of Gas Chromatography** and in several references.[41,42]

4.3 Choosing a Liquid Phase

Selecting a stationary phase for capillary GC is done using a similar thought process as for packed columns, but there are far fewer liquid phase choices readily available. First, there is a wide variety of literature available in both the research literature and in vendors' publications; this is an excellent place to start. One vendor provides a compact disk[43] compilation of over 1300 application notes, while several have application notes posted to searchable pages on the World Wide Web.[44–48] If the literature fails to produce a satisfactory result, then the ''like dissolves like'' principle may apply to the stationary phase choice.

In capillary GC there are several liquid phases that are most commonly used, plus myriad phases for specialty applications. Barry[49] provides a summary of general applications for the most common stationary phases, which is shown in Table 8. Chemical structures for the common stationary phases used in capillary GC are given in section 3.5. Since capillary columns generally have much higher plate counts than packed columns, the stationary phase choice can be much simpler. For most applications, a nonpolar phase such as polydimethyl siloxane (OV-1) or 5% phenyl polydimethyl siloxane (SE-54) can be used. More polar columns are used for specific applications, as shown in Table 8.

As the initial tool in a method development scheme, a moderate length (15–30 m) capillary column with a nonpolar stationary phase, such as polydimethyl siloxane or 5% phenyl polydimethyl siloxane, with internal diameter 0.2 or 0.25 mm and film thickness of 0.2–0.5 micron is recommended. This represents a compromise between analysis speed, high resolution and sample capacity. Once the temperature and flow conditions for a separation have been optimized as much as possible on this column, an alternative stationary phase can be selected, if the separation is not satisfactory. Klee[50] and Klee and Kaiser[51] provide systematic methods for selecting and optimizing capillary columns.

4.4 Guide to Stationary Phases for Capillary Gas Chromatography

Perhaps the most confusing part of stationary phase selection for capillary GC is that the many vendors use different designations for stationary phases that are essentially similar. A listing of the most common capillary GC stationary phases, obtained from a survey of vendors' catalogs is given in Table 9, along with a cross-reference of major vendors' designations.

5 CARE AND MAINTENANCE OF GAS CHROMATOGRAPHY COLUMNS

In both packed and capillary column GC, increasing tailing of one or more of the peaks in an analytical run, over several separations, most likely indicates degraded column performance. Depending on the types of samples being analyzed, a column may last for as little as 50–100 injections, or for several thousand. In any case, there are some general considerations in extending column lifetime, which are discussed here. For a more thorough treatment, see the monograph by Rood[52] for capillary GC and see the troubleshooting guide presented by Supelco[53] for packed columns.

5.1 Packed Columns

In general, packed columns are very rugged and easy to maintain. This is a result of the large mass of liquid phase that is present. Packed columns are more resistant to dirty solvents, or corrosive solvents, such as water or wet samples. Packed columns should be stored with the ends capped, to prevent oxidative damage over time. When they are installed into the GC, care should be taken not to overtighten the compression fittings, or leaks can result. When installed into the instrument, a gentle flow of carrier gas should be maintained at all times, to avoid oxidative damage to the stationary phase. When the liquid phase is becoming degraded from use, tailing peaks usually result. It is good practice to maintain a regular schedule of analyzing a known standard of an active analyte and to keep a record of the results. When this peak shows significant distortion over a period of several trials, column maintenance is necessary. In a glass column, discoloration of the first few centimeters of the stationary phase can sometimes be seen.

Usually, contaminants, such as nonvolatile material or contaminants irreversibly adsorbed onto the liquid phase, are found within the first few inches of the column. It is acceptable to carefully remove the glass wool plug, pour out the first few centimeters of stationary phase and to replace it with fresh packing. Tap the column gently on the benchtop or use a vibrating engraving tool to ensure even packing. Replace the glass wool plug with fresh glass wool, as this is a common source of contamination, and condition the column, as described for a new column. If the peak distortion persists, then the entire column packing needs replacement.

5.2 Capillary Columns

Capillary columns require more careful handling than packed columns, as there is a much smaller quantity of stationary phase present. In general, they should be stored with the ends sealed, to avoid oxidation of the stationary phase. Inserting the ends into a used septum makes an excellent seal, or they can be flame sealed. *Wear safety glasses at all times when handling capillary columns, as the glass capillary ends can spring out and damage the eyes upon contact*. Carrier gases should be free of organic contaminants and water, as these can also foul and contaminate the column. Typically, this requires a minimum of a molecular sieve trap to remove water and low molecular weight organic compounds and an activated carbon trap to remove higher molecular weight organic compounds. Heated gas purifier systems, available from several vendors, can also be used. The trapping material should be replaced or regenerated on a regular schedule. Carrier gases should also be high purity to avoid column and instrument contamination. Carrier gas flow should be maintained at all times that the column is installed into the gas chromatograph, to avoid oxidative damage to the stationary phase. It is good practice to leave the system running continuously, with carrier gas flowing and all zones heated to above ambient temperature. Most modern gas chromatographs have a ''gas saver'' feature to prevent excessive gas usage while samples are not running.

Tailing of peaks that were not previously tailing indicates column degradation. This diagnosis is more difficult in a capillary GC system than in a packed column system, as the column is typically separated from the inlet, where contamination is likely to occur. Thus, inlet contamination should be ruled out as the cause of tailing or distorted peaks, before column contamination is considered. As with packed columns, the contamination typically occurs within the first few centimeters of the capillary. If column contamination is suspected, the easiest treatment is to cut the first few centimeters from the column and discard it, and then to re-install the column into the gas chromatograph. Be careful to follow the manufacturer's directions for cutting and re-installing the column, or the contamination can be made worse. Usually, this cutting procedure can be applied several times, before too much cutting reduces column performance. When installing the column, take care to avoid sharp bends in the tubing and contact with the oven wall or wire cage hanger. These can cause stress points or hot spots that can lead to breakage, leaks or stationary phase degradation.

Before using a column, the minimum and maximum operating temperatures, which are usually listed in the accompanying literature, should be checked and the column should not be operated below the minimum or above the maximum temperature. Below the minimum temperature, the polymer may solidify or become glassy, preventing absorption of analyte molecules and adversely impacting retention. As the maximum temperature

is approached, the stationary phase itself begins to decompose, leading to vaporization of the decomposition products. These appear as a rise in the baseline, known as column bleed. At temperatures exceeding the maximum temperature, the column bleed becomes excessive and can damage the column or detector. Approximate maximum temperatures for common stationary phases are provided in Table 8.

The brown polyimide coating also deserves mention, as it gives the capillary column its tensile strength and flexibility; however, it, too can degrade over time. Usually, a darkening of the brown color indicates this. Beware that the column may become brittle and easily break at continuously heated zones, such as the inlet or detector. Special care should be taken if the column is placed into long transfer lines such as those used for GC/MS.

5.3 Quality Testing

There are several general methods for evaluating the performance of capillary columns. For both packed and capillary columns, perhaps the best method is to monitor one's own samples. Look for changes in the peak shape and area over time for a known standard. A column which may show poor performance in one application, such as acid analysis (acids are strongly adsorbed on capillary columns in which the deactivation of the silica tubing was poor) may be acceptable for another such as hydrocarbons. Today, most column vendors provide a test chromatogram with every column that provides some indication of the column's supposed ''quality''. These should not be used to compare columns from different vendors, as they are determined under widely varying temperature, flow and injection conditions, which can have dramatic effects on the peak shapes. Figure 4 shows a test chromatogram and data from a typical column vendor.[54]

In 1979, K. Grob et al. developed a standard quality test method for capillary columns, with an improved method described in 1981.[5,6] According to Grob, a quality test should contain enough components to provide the needed information, should provide complete information from a single chromatographic run, should be general for all stationary phases, provide some quantitative information and be standardized to allow column comparison. The Grob test is temperature programmed, and evaluates separation efficiency, adsorption of several types of components, and the actual column film thickness.

Separation efficiency can be measured by evaluating the Trennzahl[55] number (Equation 9):

$$\mathrm{TZ} = \frac{t_{\mathrm{R}}(2) - t_{\mathrm{R}}(1)}{W_{\mathrm{h}}(1) + W_{\mathrm{h}}(2)} - 1 \qquad (9)$$

for two homologs. This is essentially the difference between the retention times divided by the sum of peak

Figure 4 Typical column quality test chromatogram 1: pentane; 2: undecane; 3: 4-chlorophenol; 4: 1-decylamine; 5: tridecane; 6: methyl caprate; 7: tetradecane; 8: acenaphthylene; 9: 1-dodecanol; 10: pentadecane.

widths and it expresses roughly the number of peaks that could fit between two adjacent peaks on a chromatogram. A larger Treunzahl number indicates a more efficient column. It is noted that the classical efficiency measure, N, the number of theoretical plates is not easily applied to temperature programmed separations. The Trennzahl number is a measure of the number of peaks of width similar to the homologs that can fit between the homolog peaks.

There are several indications of excessive adsorption or mixed retention mechanisms. These include broadened Gaussian peaks, tailing peaks, reduced peak area and misshapen peaks with long retention. Usually, all of these result in reduced peak height, as compared to a normal Gaussian peak. An abnormally low peak area for a given component usually indicates irreversible adsorption somewhere in the system. Hydrogen bonding is characterized by peak tailing and can be examined using a primary alcohol. An aldehyde can provide an indication of excessive nonhydrogen bonding adsorption, while acidic and basic components can be used to study those interactions. Using these considerations, Grob developed

Table 10 Components of the Grob test mixtures for assessing the quality of capillary GC columns[5,6]

Compound	Purpose
Methyl decanoate	Determination of separation efficiency; second standard for 100% peak height used in adsorption calculations
Methyl undecanoate	
Methyl dodecanoate	
n-Decane	Standard for retention index and 100% peak height adsorption calculations
n-Undecane	
n-Dodecane	
1-Octanol	Hydrogen bonding adsorption on silicones
Nonanal	Non-hydrogen bonding adsorption
2,3-Butanediol	Hydrogen bonding adsorption on polyethylene glycols
2,6-Dimethylaniline	Acid base interactions
2,6-Dimethylphenol	Acid base interactions
Dicyclohexylamine	Acid base interactions (sterically hindered)
2-Ethylhexanoic acid	Acid base interactions

two test mixtures, for polar and nonpolar columns. The components of these mixtures and their purpose are given in Table 10. The introduction of the Grob test led to many future developments in column deactivation procedures. The specific procedures for using the Grob test mixtures for column evaluation and comparison are given in Grob.[5,6] The test mixtures used by the column vendors are typically variations of the Grob mixture.

6 RECENT AND FUTURE DEVELOPMENTS

Packed columns currently are used for a fairly stable 20% of GC analyses. Today, they are used for specific applications, such as gas analysis, solvent analysis, process control and education that benefit from the large volume of stationary phase, lower resolution and simple instrumentation. Majors,[56] who polled both the readership of ''LC-GC'' magazine and several recognized experts, recently surveyed this. Thus, much of the recent developments in GC stationary phases have been in the improvement of capillary column technology.

With the explosion in capillary GC use that occurred in the 1980s, and the development of quality tests, such as the Grob test mixture, many of the developments have led to better deactivation of the silica tubing and stationary phase materials themselves, improved temperature stability and to a much wider variety of stationary phases, many designed for specific applications, such as United States Environmental Protection Agency (USEPA) approved methods. A recent fundamental survey of GC[57] shows 76 references in liquid phase developments and 70 articles describing research on solid adsorbents and supports for the period 1994–1997. Much of the research on solid materials has been in the study of surface chemistry and deactivation procedures. Work on liquid phases has been on the development of new phases for specific difficult applications, such as the analysis of light hydrocarbons on capillary columns, and the development of high selectivity for specific compound classes, such as polycyclic aromatic hydrocarbons, substituted benzenes, and chiral separations. Developments in chiral stationary phases, organic polymers and inorganic liquid phases are described here.

6.1 Liquid Phases for Specific Applications

The column vendors have been introducing liquid phases tailored to specific applications and methods for several years. A survey of the major vendors shows liquid phases available for a variety of specialty applications, ranging from specific compendial methods to classes of analytes. Table 11 provides a summary of some applications for which specially formulated liquid phases are available.

6.2 Chiral Stationary Phases

The development of chiral stationary phases for GC has been an active research area in GC for many years. Cyclodextrins and derivatized cyclodextrins are predominantly used for chiral GC applications and have been recently reviewed in the text by Konig.[58] Due to the

Table 11 Selected commercially available specialty liquid phases and their applications

Application	Description
Thermally stable modified form of common phases; low bleed; highly inert	For GC/MS, electron capture detection and other highly sensitive analyses
35% Phenyl polysiloxane	Conformational analysis
Bonded poly(ethylene glycol)	FAME
Bis(cyanopropyl) polysiloxane	Positional and geometric isomers of polysiloxanes
Base modified polysiloxanes	Amines; basic analytes
Carbowax® amine	Primary, secondary, tertiary amines
6% Cyanopropyl phenyl, 94% polydimethyl siloxane	United States Pharmacopeia and European Pharmacopeia volatile organic contaminants methods

The major vendors provide proprietary bonded phases specifically designed for many compendial methods such as those for the USEPA and United States Pharmacopeia.

Table 12 Chiral GC applications using cyclodextrin-based liquid phases[58]

Application	Refs.
3,4-Diphenyl cyclopentene	64

DDT, dichlorodiphenyl trichloroethane.

complexity of chiral recognition, many forces are involved in generating separations on cyclodextrin columns. Typically, multiple interactions are required, which may be any or all of the following possibilities. These include hydrogen bonding,[59] van der Waals interactions,[60] size of the inclusion cavity,[61] polar interactions[62] and steric hindrance.[63] Table 12 provides a listing of applications recently described using cyclodextrin columns.

6.3 Organic Polymer Stationary Phases

As described above, most modern GC liquid phases are composed of organic polymers that are coated into capillaries or onto solid supports. Most of the recent research and development of new polymeric substances can be divided into several areas: classification of currently available materials, liquid crystals, crown ethers, substituted silicones and chemically bonded cyclic organo-siloxanes (silica gels). Research on the specific interactions that determine retention on GC liquid phases continues today, with Santiuste and Takacks describing the interaction capacity of 26 common liquid phases.[80] Rohrschneider recently reviewed work in the general area of phase constants for liquid phase characterization.[15] Several workers have employed liquid crystals as GC stationary phases. Liquid crystals have recently been employed for the separation of hydrocarbons,[81] dioxins,[82] phthalic acids[83] and polycyclic aromatic hydrocarbons.[84] Liquid crystals show promise for the separation of positional isomers of both aliphatic and aromatic compounds.[85,86] Crown ethers have been bonded to polysiloxane liquid phases to provide special selectivity for short chain alcohols, ethyl esters of carboxylic acids and substituted benzene and phenol isomers.[87,88] Sol–gel technology has recently been used to make stationary phases for capillary columns with very high surface area and thermal stability, improving both capacity and ruggedness.[89]

7 CONCLUSIONS

The liquid phase is the heart of the GC separation system. It is here where all separation occurs. Development of new liquid phase technologies began along with the invention of GC and continues to be active. The renaissance in GC development that began with the introduction of fused silica capillary columns in 1979 also strongly affected stationary phase development. Today's capillary columns are relatively inexpensive, rugged, reproducible, inert and are available in a large variety of dimensions and liquid phases. In the future, new liquid phases that are more inert, have lower bleed, or address specific chemistries will continue to be developed. Stationary phase development continues to be a very active area of GC research and development.

ACKNOWLEDGMENTS

This article is respectfully dedicated to the memory of Professor Mathew Petersheim (1954–1998), friend, mentor and chair of the Seton Hall University Department of Chemistry from 1994–1996, who was taken from us far too soon.

LIST OF SYMBOLS

α	selectivity
β	column phase ratio
d_p	packing particle diameter
d_f	stationary phase film thickness
D_M	diffusion coefficient of an analyte molecule in the mobile phase
D_S	diffusion coefficient of an analyte in the stationary phase
ΔG°	standard free energy change
γ	tortuosity factor in the van Deemter Equation – related to the column packing
H	height equivalent to a theoretical plate
K	partition coefficient
k	retention factor
λ	packing factor – a constant in the van Deemter Equation related to the packing efficiency of the particles
μ	average linear gas velocity
N	number of theoretical plates
N	carbon number of the normal alkane eluting immediately before an analyte
$N+1$	carbon number of the normal alkane eluting immediately after an analyte

R	gas constant
r_c	radius of a capillary column
R_s	resolution
t_R	retention time
t'_R	adjusted retention time ($t_R - t_M$)
t_M	gas hold-up time
T	temperature
TZ	Treunzahl Number

ABBREVIATIONS AND ACRONYMS

AW	Acid Washed
DDT	Dichlorodiphenyl Trichloroethane
DEGS	Diethyl Glycol Succinate
DMDCS	Dichlorodimethyl Silane
FAME	Fatty Acid Methyl Esters
GC	Gas Chromatography
GC/MS	Gas Chromatography/Mass Spectrometry
GLC	Gas–Liquid Chromatography
GSC	Gas–Solid Chromatography
HETP	Height Equivalent to a Theoretical Plate
HMDS	Hexamethyl Disiloxane
NAW	Not Acid Washed
RI	Kovats Retention Index
USEPA	United States Environmental Protection Agency

Two-dimensional gas chromatography (2-D GC) is a logical extension of gas chromatography (GC) carried out on a single column. It provides physical resolution of components which are difficult to analyze by other means. Two different arrangements are possible in 2-D GC. In the conventional mode, effluent fractions from the primary column are switched onto a secondary column of different polarity. In the comprehensive mode, the entire effluent from the primary column is examined by the secondary column. The major advantage of 2-D GC is the enhancement of peak capacity. Statistical methods of overlap theories predict severe limitations of the resolution of components in multicomponent mixtures. The problems are exacerbated when components form clusters, such as in the analysis of isomers. The determination of target analytes at trace levels also poses unique challenges. Selective detectors, in particular mass spectrometry (MS), can provide answers when merged components are capable of producing distinctive spectra. MS can compensate for poor chromatographic resolution in many cases but it cannot be applied for the deconvolution of isomers and closely related substances. In this situation, 2-D GC is the only choice.

Instrumentation in conventional 2-D GC is based on one of two different effluent switching technologies. A valve can be used to divert the effluent from the primary column to a secondary column of different selectivity. In this arrangement, the sample inevitably comes into contact with the metal of the valve body. The other design is based on fluidic switching by application of a difference in pressure in the interface between the columns. This technology, generally referred to as Deans switching, can avoid metals in the sample flow path but it is technically more difficult than valve-based technologies.

Comprehensive 2-D GC involves a focusing step. The effluent from the primary column is periodically injected into a high speed column in the form of narrow chemical pulses. The separation on the secondary column must be complete (or nearly complete) before the next pulse can be injected. The secondary column is polar, i.e. substances that have similar boiling points but differ in polarity can be resolved in the second dimension. The separations process is continuous and resembles data acquisition in routine gas chromatography/mass spectrometry (GC/MS). One of the true advantages of comprehensive 2-D GC is that the separations mechanisms on both columns can be decoupled, leading to true orthogonality. Components with similar properties fall into clearly defined data spaces. The chromatograms show a measure of order which is useful in substance identification and group type analysis.

Comprehensive 2-D GC is still in its infancy. There is much room for improvements, including in the data acquisition/display area. Conventional 2-D GC, however, is mature. Because of the complexity of 2-D GC instrumentation, selective detection, i.e. GC/MS, is usually preferred where it is applicable. Many applications based on 2-D GC have been published. The analysis of flavors/fragrances, petrochemicals and persistent organohalogens in the environment by 2-D GC offers distinctive advantages over competing technologies.

1 INTRODUCTION AND HISTORICAL PERSPECTIVE

GC is undoubtedly the most widely used technique for the separation of volatile components. It is amenable to the analysis of a wide range of organic and inorganic materials. Some of the strongest aspects of GC come from its operational characteristics. It is relatively easy and inexpensive to achieve high separation power and short turnaround times. The wide array of excellent general and specific detectors available for GC is perhaps one of its biggest attractions. There is no other instrument in chromatography that can offer this level of performance. GC occupies an important position in

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

the array of separation techniques. Although it is not the oldest form of chromatography, it was the first one to mature as an instrumental technique. Relatively sophisticated instrumentation based on packed column technology and flame ionization detection or electron capture detection became commercially available in the late 1950s and early 1960s. The separation power and versatility of capillary column GC was demonstrated early on. Efficient metal capillary columns with apolar stationary phases were relatively easy to produce but problems due to active surfaces could not easily be conquered.[1] The introduction of glass as a column material opened an avenue to overcome this major hurdle.[2] Glass drawing machines became commercially available and aided in the development of this column type. Many recipes were offered for the production of truly inert surfaces and stationary phase coating techniques were perfected.[3] Immobilized stationary phases, introduced in the early 1970s, were another major development.

Many scientists have contributed to the advancement of capillary column technology during these years. History records many individual inventions and advancements. No individual was as influential in the overall development of glass capillary column technology as Grob.[4] One might have assumed that chromatographers would jump at this new development and substitute packed column applications demanding high resolving power with capillary column based methodology. Unfortunately, little progress was made in this respect. Glass proved to be too difficult to handle on a routine basis and capillary column dedicated instruments were not built because of patent infringement issues. The situation again changed dramatically in 1979 when a scientist working for the Hewlett Packard Company adapted glass fiber optics technology to GC.[5] Flexible fused silica capillary columns quickly replaced glass capillary column technology. This column type was not only easier to handle from a practical perspective but a wide variety of commercial columns were introduced onto the market shortly after the basic patent expired. Capillary column GC finally took off. It is not surprising that many scientists pushed the exploration of the principles of GC to its limits. The introduction of an entirely new family of affordable spectrometers as on-line detectors made a major impact. The practical limits of GC as a tool and as a technique were approached in more than one area. Although GC inherently has high resolving power, it has limitations in many areas, including the resolution of highly complex samples.

2-D GC is one of the most effective techniques to deal with multicomponent samples, especially those consisting of substances having a wide range of polarities. The principle is simple: components that experience similar retention characteristics on one particular stationary phase are subjected to an additional separation step on a second column of different selectivity. Two components of approximately the same boiling point which elute on an apolar phase as a single peak may have different functional groups. Differences in polarity, polarizability, etc., can then be exploited. This process can be carried out off-line but this technology is very difficult for trace components. On-line techniques rely on some type of column switching hardware that allows the transfer of an effluent fraction between the columns. This type of manipulation, generally referred to as heartcutting, GC/GC, or 2-D GC, has been used since the mid-1950s, primarily in process control. Simmons and Snyder[6] are credited with the first use of 2-D GC in general analysis. In principle it is possible to resolve component(s) from a mixture as long as a set of stationary phases is available that differentiates between the target compound(s) and its interferences. Full characterization of a complex sample requires the transfer of a large number of individual cuts. The process becomes laborious and time-consuming. In practice, there are other hurdles to overcome as well. As long as only a single heartcut is being made, it is possible to correlate a secondary chromatogram to a transfer from the primary column. This advantage is lost when multiple heartcuts are made in the course of a single run. Since stationary phases act independently, components from individual transfers tend to mingle and can thus no longer be correlated.

A technical solution to carry out multiheartcut 2-D GC has been developed. Narrow slices of effluent are periodically injected from a primary column into a short, high-speed secondary column. Components which are not resolved in the first dimension undergo a second separation step. The process is analogous to routine GC/MS and is known as comprehensive 2-D GC. In both processes, the entire sample is sliced into narrow packets for further examination. The practical implementation of comprehensive 2-D GC is the brainchild of Phillips who invented a thermal modulator as a sample introduction device. Comprehensive 2-D GC is less than 10 years old.[7] As with any new technology, there are still many obstacles to be overcome. The technical side is moving along nicely. New ground had to be broken in several areas, notably in data acquisition and display. The situation can be compared to the early days of GC/MS when analog to digital interfaces and computers were slow and of limited capacity. Looking at the steady progress in GC/MS, one has to be optimistic that current stumbling blocks will eventually fall by the wayside.

The inventors and proponents of comprehensive 2-D GC have not done a very good job of ''selling'' their invention. Many chromatographers who are quite knowledgeable remain skeptical because the fundamental principles, technical approaches and strengths/weaknesses of

this new tool have not been adequately explained. There is also a lack of general applications. At present only one small firm[8] has secured the rights to exploit the patents issued for the basic design.[9,10] No more than around a dozen laboratories in the world are actively pursuing research in a major way in this area.

2-D GC is a multifaceted technique. Its major use is in the physical separation of multicomponent mixtures but there are other areas of application as well. The preparative scale isolation of trace components in a complex mixture is an example. Hardware differs for conventional heartcutting-type operations and comprehensive 2-D GC differs significantly. It is described in separate paragraphs.

2 PEAK CAPACITY AND OVERLAP IN GAS CHROMATOGRAPHY

Two-dimensional separation procedures become especially important when complex samples consisting of hundreds of components must be analyzed. Resolution in GC depends on several factors. For isothermal conditions, Equation (1) applies:

$$R_s = \frac{1}{4}\left(\frac{\alpha - 1}{\alpha}\right)\left(\frac{k'}{k' + 1}\right)\sqrt{\frac{L}{H}} \tag{1}$$

where R_s is resolution, α selectivity, k' solute retention factor, L column length, and H theoretical plate height. Since the number of theoretical plates is proportional to column length (Equation 2)

$$N = \frac{L}{H} \tag{2}$$

where N is the number of theoretical plates, resolution varies with the square root of column length. Retention, and thus time of analysis, is however directly proportional to column length. In practice, resolution also depends on other factors such as the relative magnitude of the peaks being resolved. Merged peaks of approximately equal height can easily be recognized and quantitated with good accuracy at less than unit resolution. As peak ratios continue to deviate, merged peaks become less distinctive. In practice, it is not uncommon to quantitate adjacent components in a chromatogram that differ in concentration by several orders of magnitude.

Even though Equations (1) and (2) are useful in describing fundamental relationships in GC, they are very limited in practice. The vast majority of GC separations are carried out under temperature programmed conditions. Unfortunately, the effects of temperature programming on resolution are complex and difficult to describe. An alternative way to evaluate the separation power of a column under both isothermal and temperature programmed conditions is the use of the peak capacity concept. Peak capacity is defined as the maximum number of component peaks that can be packed side by side into the available separation space at a given resolution.[11] The frequency of component overlap is thus a function of peak capacity. For isothermal runs, peak capacity n_c can be related to the number N of theoretical plates as shown in Equation (3)[10]

$$n_c = \theta N^{1/2} \tag{3}$$

where n_c is peak capacity, and θ is a variable that depends on retention time range. The determination of peak capacity under conditions of temperature programming is complex.[12] In conventional capillary column GC, typical peak capacity values are in the range of a few hundred. It would appear that peak capacities of this magnitude would be adequate for all but the most complex samples. Unfortunately, this is not the case. Davis and Giddings[13] developed a concept based on the random distribution of component peaks in chromatographic separation space. The mathematical treatment which is based on Poisson statistics is now commonly referred to as the statistical model of overlap (SMO) theory. It has been refined and expanded for the last 20 years by Davis,[14] a former Giddings student, and his group. Alternative concepts for the evaluation of statistical peak overlap have also been offered.[15,16] Regardless of the model used, the relationships are complex and the findings are not easily applicable in practice. Simple calculations show, however, that single column systems are not capable of producing separation numbers which are adequate even for samples of only moderate complexity.

SMO theory can be used to predict resolution as a function of several variables. The number of peaks p observed in a chromatogram and the expected component number m in a sample are related to column peak capacity n_c as shown in Equation (4)

$$p = m\mathrm{e}^{-m/n_c} = m\mathrm{e}^{-\alpha} \tag{4}$$

where α is the saturation factor. In the special case where the expected number of components is equal to the peak capacity of the column at hand, the function reaches a maximum. With random spacing, only 37% of the peaks can theoretically be resolved. Resolution becomes an exponential function of peak capacity, as shown in Equation (5)

$$\left(\frac{p}{n_c}\right)_{\max} = \mathrm{e}^{-1} = 0.3679 \tag{5}$$

In practical chromatography, the results are even worse since factors such as peak distortion, peaks differing in magnitude, instrument noise and similar disturbances

have not been considered in this model. The number of single component peaks s, shown in Equation (6), is smaller than p,[14]

$$s = m\mathrm{e}^{-2m/n_c} = m\mathrm{e}^{-2\alpha} \tag{6}$$

The number of peaks representing single components cannot exceed 18% of the available peak capacity n_c. The ratio s/m represents the fraction of all components isolated as single component peaks. It can be expressed as probability P_1, as shown in Equation (7):

$$P_1 = \frac{s}{m} = \mathrm{e}^{-2\alpha} \tag{7}$$

As expected, the occurrence of single component peaks is linked to saturation.

Some examples can illustrate the consequences of statistical component overlap and point toward potential remedies. Consider a sample consisting of 50 components which needs to be analyzed on a column having a peak capacity n_c of 100. It would appear that most components should be adequately resolved, since twice the necessary peak capacity is available. Only 18 substances or 36% of the sample will however be represented as single component peaks.[13] This is a clear disappointment. Decreasing the level of saturation improves the chance of obtaining single component peaks but the gains are painfully slow. At $\alpha = 0.5$ and $\alpha = 0.25$, P_1 increases to 37% and 61%, respectively. To elevate P_1 to 82%, saturation α must be lowered to 0.1, i.e. a 10-fold excess of peak capacity must be available. Equations (4) and (7) show that the 100-component sample requires a column peak capacity n_c of 288 for a relatively modest probability P_1 of 50%. Under favorable circumstances, this separation can be achieved on a column producing 100 000 theoretical plates. To increase the probability to 90% and 99%, respectively, columns of 4 000 000 and 500 000 000 theoretical plates are required. This type of performance is clearly outside the range of most GC instruments. The current limit of single column GC is around 4 000 000 theoretical plates, corresponding to a peak capacity n_c of approximately 1000.[17] Gasoline, a sample of moderate complexity, was analyzed on such a system. The chromatogram produced 970 distinguishable signals, mostly in the form of merged peaks. The results from this analysis are impressive but it took 15 h to complete the separation.

The achievement of high efficiency carries another price tag. Since plate height H is approximately inversely proportional to the inverse of column diameter, small bore columns have to be used. Columns with small internal diameter not only produce a high pressure drop but the amount of stationary phase available also becomes a limiting factor.[18] Columns of 50–100 μm internal diameter have low sample capacity and are difficult to operate.[19] Recycle chromatography is an alternative to overcome both limitations. This technique is based on the use of two relatively short conventional capillary columns connected via a low dead volume valve. The effluent fraction which requires further resolution is alternatively routed through each of the columns by turning the valve at the appropriate time. A recycle unit consisting of two 20-m segments produced over 2 000 000 theoretical plates for a run consisting of 20 cycles.[20] Large peak capacities can easily be obtained. The resolution of isomer pairs such as pristine and phytane which requires very high efficiencies on any stationary phase can be accomplished. Recycle operations are quite amenable to 2-D GC because they are already based on the use of valves. There is a problem however with the timing of valve switching. A very low dead volume in-line detector is necessary or some of the effluent has to be diverted to an off-line detector. The prospects of recycle GC are exciting but these problems must first be overcome to make it truly competitive.[21]

2-D GC can provide an alternative to single column GC when highly efficient systems are required. There are two conditions that must be fulfilled: (1) the components must be subjected to two separation steps (mechanisms); and (2) once separation has been achieved in any single step, the substances must remain separated.[22] The power of 2-D GC comes from the use of complementary stationary phase selectivities and the utilization of the "empty space" in the second column. Figure 1 shows a basic diagram of the separation concept in a coupled column system. It is obvious that narrow heartcuts reduce the chances of coincidental overlap in the second column. From a practical point of view, one needs to consider additional factors.

- Components which have undergone peak broadening in the primary column continue to do so in the secondary column. Final peak widths may become unacceptable.

Figure 1 Schematic diagram of idealized 2-D GC showing a single heartcut.

- Peaks that are already partially separated may merge in the secondary column due to ''a mixed phase mechanism''.
- It may be difficult to correlate the retention times of components on both columns unless one can keep track of their relative movements.

The installation of an intermediate trap between the columns is a way to overcome some of the hurdles. Solutes can be refocused and reintroduced as narrow pulses. In this manner, relatively broad cuts can be taken. As the width of the cut is widened, an increasing number of substances is introduced and a point of diminishing return is eventually reached. The other extreme is the transfer of effluent on the timescale of the width of a single peak. Narrow heartcuts are likely to produce only a few components in secondary chromatograms. There is an obvious balance between the number of transfers, complexity of secondary chromatograms, and time requirements.

The major use of heartcutting in 2-D GC is the physical separation of a few trace target compounds in the presence of major interferences. The complete two-dimensional characterization of a sample requires a different approach. Figure 2 shows an arrangement where adjacent heartcuts are performed within the same run. The maximum peak capacity $n_{c(max)}$ of such a system is approximately given by Equation (8):

$$n_{c(max)} = \bar{n}_c \times \text{number of columns} \qquad (8)$$

where $\bar{n}_c$ is the average peak capacity of the columns used in the system. Two independent secondary columns allow the separate development of individual heartcuts. Components eluting at the interface between the individual transfers will be found in both secondary chromatograms. All other substances will appear in only one of the chromatograms. The components which have been resolved on the first column thus remain separated. It is obvious that the complete characterization of a sample in an assembly of multiple secondary columns is not practical. As an alternative, an arrangement using multiple parallel traps can be used.[23,24] Effluent from the primary column is essentially stored in these traps. This approach differs from the conventional heartcut-type operation indicated in Figure 1. The contents of each trap can be injected into the secondary column, one at a time. The ambiguity introduced by multiple heartcutting is thus eliminated. There are some practical problems, as expected. The apparatus is complicated and the adsorbents used in the traps may have a tendency to interact with some of the more delicate sample components. The use of recently introduced polysiloxane-based trapping materials can overcome activity problems.[25]

The most effective way to improve the total peak capacity of a system is the addition of a large number of secondary columns. Figure 3 shows the equivalent of a two-dimensional separation in planar chromatography. The hardware giving access to this type of dispersion in GC is actually quite simple, at least in principle. The effluent is focused as it emerges from the end of the primary column. It is then periodically injected as a series of sharp pulses into a single secondary column. Elution time from the secondary column is synchronized to the frequency of injection from the primary column, i.e. the last component must have left the secondary column before the next pulse is injected. This type of operation is referred to as *comprehensive* 2-D GC because the entire sample is processed in a comprehensive manner.

Figure 2 Superposition of two adjacent secondary columns of a coupled column system.

Figure 3 Idealized presentation of the peak capacity of a comprehensive two-dimensional system. Individual peak capacities are represented by the number of adjacent profiles.

Table 1 Comparison of conventional (single column) GC with various modes of 2-D GC[a,b]

	Conventional single column GC	Heartcut 2-D GC	Parallel trap 2-D GC	Heartcut recycle 2-D GC	Comprehensive 2-D GC
Simple mixture	++	+	+	+	+
Complex mixtures					
One or a few compounds of interest	+	++	++	+	+
Many compounds of interest	−	+	++	−	++
"All" compounds of interest	−−	+/−	+	−−	++
Resolution	+/−	+	+	++	++
Complexity	++	+	+/−	−	−
Flexibility	++	+/−	+/−	−	−
Robustness	++	+	+/−	+/−	+/−

[a] Symbols (++, +, +/−, − and −−) indicate suitability.
[b] Reproduced from H.-J. de Geus et al., 'Two-dimensional Gas Chromatography for Environmental Analysis', *Trends Anal. Chem.*, **15**, 398–408, © 1996, with permission from Elsevier Science.

The maximum peak capacity of such a system can be approximated by Equation (9):

$$n_{c(max)} = n_{c(1)} \times n_{c(2)} \quad (9)$$

where $n_{c(1)}$ and $n_{c(2)}$ are the peak capacities of the primary and secondary columns, respectively.[26] The term GC × GC which is used interchangeably with the term comprehensive 2-D GC emphasizes the multiplicative nature of individual column peak capacities in the combined system. Although there are some restrictions on the optimal use of this technology, it is clearly the only practical route toward the achievement of very high peak capacities. At the present time, peak capacities n_c approaching 54 000 have already been demonstrated.[27]

Instrumentation and methodologies of conventional 2-D GC and comprehensive 2-D GC differ in many aspects. There are distinct advantages and disadvantages to each type. It is difficult to make generalizations because the suitability of a particular type of 2-D GC depends on details of the particular instrument design and on the problem at hand. Table 1 is a general overview of advantages and disadvantages of the basic instrument types available.[28] Aspects of conventional 2-D GC and comprehensive 2-D GC are presented separately.

3 CONVENTIONAL TWO-DIMENSIONAL GAS CHROMATOGRAPHY

3.1 Instrumentation and Procedures

2-D GC instrumentation consists of an arrangement of two columns where one of the columns acts as inlet for the other one. Functional instruments require a great deal of attention to the interaction between sample components and surfaces and to unswept volumes in interfaces. Contact of sample components with unsuitable surfaces has the potential of causing undesirable reactions or tailing due to adsorption. Excessive transit times are a source for experimental dilution and band broadening. Interestingly, little information has appeared in the recent literature on new developments and refinements of 2-D GC hardware. Most of the developments in 2-D GC date back to the 1970s and 1980s. This is in stark contrast to many other areas of GC where improved technology has driven instrument design to new heights.

The introduction of low cost spectrometric detectors, in particular the mass spectrometer, has diverted much interest away from 2-D GC. The emergence of routine MS in conjunction with GC is the main reason why 2-D GC has not flourished. These techniques are in competition with each other. Table 2 summarizes trends in both disciplines. The number of publications in GC has held relatively steady, as opposed to liquid chromatography which experiences slow but steady growth. The use of GC/MS is still on the rise although it has slowed somewhat. By contrast, 2-D GC in all its forms is insignificant. It has stagnated over the last 10 years.

Benchtop-type GC/MS is relatively inexpensive, versatile and has a user interface conducive to the production of large volumes of data. In contrast, 2-D GC requires fine-tuning and is relatively difficult to carry out. In many

Table 2 Number of publications in the *Chemical Abstracts* database, according to keyword index, reported in 4-year increments

Year	GC	GC/MS	2-D GC
1978	4497	894	11
1982	4761	994	16
1986	4643	1237	43
1990	4049	1542	57
1994	4056	2258	56
1998	3992	2541	62

Chromatogr.*, **471**, 173–185, © 1989, with permission from Elsevier Science.)

situations, mass spectra of target compounds are sufficiently different from the interfering background to permit characterization and quantitation with little or no chromatography. Mass spectral selectivity is often substituted for chromatographic resolution. Unfortunately, there are many pitfalls to this approach. A great deal of unreliable data may be generated from the inappropriate use of MS. There are many situations where the physical separation of target compounds is the only viable option. MS can generate highly reproducible data which may suffer from the same interferences. High precision is often taken as an indicator for accuracy. Interferences in MS are very common because related substances produce common ions. Strict quality control measures must be put in place to safeguard against poor data quality.

Conventional 2-D GC instrumentation offers a wide variety of options. In the most simple case, the columns are connected via a microvalve and are placed in a single oven. Complex instruments feature sophisticated pressure balanced pneumatic switches under conditions of mass flow control. This principle is often referred to as a Deans switch, after its original proponent.[29] A secondary inlet for the injection of calibration standards into the second column and a monitor detector between the two columns are useful, almost necessary, additions. Other features include dual ovens, a computer controlled interface responding to events in real time, an intermediate trap and a sophisticated selective detector, such as a mass spectrometer, infrared spectrometer, or atomic emission spectrometer. In special cases where the on-column enrichment of trace components is required, a parallel trap accessory may be a part of the instrument. Figure 4 shows the design of such an instrument. This particular design is geared toward the on-line evaluation of flavors and fragrances and features two Deans-type switches.[30] This instrument can be equipped with a variety of detectors, including a sophisticated isotope ratio mass spectrometer.[31] Isotope ratio MS is an important tool to uncover adulteration in the food industry and study details of biosynthesis and metabolism.[32] Valve-based instruments can also be quite sophisticated. Figure 5 shows the design of such an instrument.[33] Only one of the five valves actually comes into contact with the sample. The other units are used to carefully balance pressures and turn on/off the flows in the rest of the instrument. Vacuum can also be used to switch effluent between columns. The effluent is virtually sucked into an interface, as it emerges from the primary column.[34–36]

Contact of the sample with surfaces other than well deactivated glass or fused silica is of much concern. It is obvious that valve-based systems must contain metal that may cause problems with labile compounds. Instruments equipped with Deans-type switches can totally avoid metals in the effluent flow path.[37] Arrangements based on fused silica column technology permit the use of friction-type connectors, tees and crosses which are made of glass and can thus be well deactivated.[38] Metal, in particular stainless steel, has perhaps an unjustified bad reputation as a poor chromatographic surface. Instruments equipped with both valves and Deans-type switches have been compared for potential artifacts. The results are inconclusive.[39] Oxygenated compounds, in particular free acids, anhydrides, and aldehydes, are usually good indicators of residual activity.[40,41] It

appears that noble metals such as Pt/Ir may not be as inert as many users imagine. There is at least one report on the tautomerization of α-ketols on a commercial 2-D GC instrument that uses a small piece of Pt/Ir in its interface.[42] Significant advances have been made in the deactivation of metal surfaces within the last 5 years. Columns are now available that can compete with fused silica in every aspect, including inertness. The controversies point out that each situation should be evaluated on a case-by-case basis.

Compared to other developments in GC, relatively little progress has been made in the advancement of 2-D GC instrumentation over the last 20 years. Commercial aspects have also been rather subdued. Most instrument manufacturers seem to be willing to modify or adapt instruments for 2-D GC. A dedicated instrument however is available from only one source, the Siemens Co. This instrument is based on a Deans switch and has a dual oven configuration. The design is largely based on the work of Schomburg and his group who have pioneered many developments in the design of 2-D GC instrumentation.[43–45] Figure 4 shows some details of the heart of this instrument, referred to as a live switch. There are several suppliers and specialty companies that

provide components for the conversion of conventional instruments to 2-D GC use. The DANI, SGE, AC Controls and Gerstel companies provide accessories and instrument modification based on the Deans principle. These firms are headquartered in Italy, Australia, Holland and Germany but have outlets in the USA and many other countries. The switching components include external computer controlled solenoid valves. Mass flow control is a preferred way to ensure the stability of switching under conditions of temperature programming.[46] The timing of effluent switching can be a very critical issue. It is sometimes important to divert a single peak, such as an unresolved pair of enantiomers, into a secondary column. One of the most elegant ways to ensure precise cutting is to use an internal standard. This principle has been implemented. The system determines the accurate position of a cut by calculation of retention indices and makes adjustments to compensate for changes.[47] The pressure–flow relationships in Deans-type switches are now well understood.[48]

The use of an intermediate trap between the columns raises challenges but also provides for additional flexibility. A trap must be capable of the retention of the target analyte and, more importantly, allow rapid reinjection. A variety of designs have been offered.[49,50] Details of the performance of individual components and instrumentation are beyond the scope of this discussion. The reader is referred to the original literature. Several reviews are available on the subject.[44,51–56] There is also extensive coverage of 2-D GC in general textbooks.[57,58] It is interesting to note that only a single review has appeared within the last 8 years.[59]

3.2 Practical Aspects

Even though the major use of 2-D GC is for the resolution of target components in complex mixtures, it is also useful in other areas. A general lack of sample capacity is a major problem associated with the use of narrow bore thin film columns. Multiple injections can be used to build up the targeted trace component(s) to a level where adequate detection or preparative scale isolation is feasible. Instruments with intermediate traps or parallel traps are particularly suitable for this purpose.[60,61] Analysis time is another major issue. Column flow can be reversed after the heartcut has taken place. Backflushing techniques can be incorporated into heartcut operations. This approach saves much time in routine analysis.

The complete characterization of a complex sample is perhaps the most difficult of all situations. The analysis of tobacco smoke is the classical example of a truly complex sample. Tobacco smoke condensate consists of thousands of substances at the parts per million level and above. The substances appear in a wide range of concentrations, are often multifunctional and may have both acidic and basic properties. Figure 6(a) shows a chromatogram of a tobacco essential oil on the first column of a two-dimensional system.[62] The resolving power of the column is modest but it is apparent that the separation, especially of minor components, would still be inadequate on a more efficient column. Figure 6(b) presents chromatograms derived from two of the heartcuts. Approximately 1500 peaks were observed and 300 were identified using mass spectra and retention indices. It is likely that secondary chromatograms still contain unresolved components. This is a situation where another separation step may be necessary.

3.3 Selected Applications

2-D GC applications have been described for many analytical problems amenable to GC. There are three distinctive areas where 2-D GC has really made an impact and is thus in routine use. These are in certain aspects of petroleum chemistry, the analysis of persistent chlorinated substances in the environment and the food/fragrance industry. The classification of crude oils and petroleum-based distillates is the oldest and most traditional application of conventional 2-D GC. Petroleum contains mainly hydrocarbons and heteroatom compounds. Both groups are of interest. Heteroatom compounds include the elements sulfur, nitrogen and oxygen. Substances of this type are usually undesirable because they are potent catalyst poisons and potential air pollutants. Petroleum-type samples are often subjected to group specific reactions or are selectively determined by spectroscopic methods. The American Society for Testing and Materials (ASTM) has issued a large number of individual methods. Hydrocarbon analysis makes use of many disciplines of chemistry. Hyphenated techniques such as liquid chromatography/gas chromatography (LC/GC) and GC/MS are particularly useful. One of the most common types of analysis involves the speciation and quantitation of paraffins, isoparaffins, olefins, naphthenes and aromatics, abbreviated as PIONA. The routine determination of petroleum products in terms of these substance classes is very important. As an example, high olefin content is undesirable because these compounds are unstable. The refinery engineer requires reliable data to optimize the blending of process streams and for many other critical operations.

Hydrocarbons in petroleum are extremely complex. There are some 4×10^7 potential paraffin isomers in the C_{10} to C_{25} carbon range alone.[63] PIONA analysis by 2-D GC is carried out in instruments that consist of a series of valves, traps, absorbers and reactors. Effluent is switched back and forth among as many as five columns. Each column is optimized to deal with

Figure 6 (a) Chromatogram of a tobacco smoke essential oil on the primary column (column 15 m × 0.53 mm × 1.0 µm, DB-Wax), indicating the position of heartcuts. (b) Secondary chromatograms (column 30 m × 0.25 mm × 0.25 µm, DB-1701) of two adjacent heartcuts 7 and 8, as indicated in (a). (Reproduced from B.M. Gordon et al., *J. Chromatogr. Sci.*, **26**, 174–180 (1988), by permission of Preston Publications, a division of Preston Industries, Inc.)

a particular range of compounds. A dedicated PIONA analyzer was originally introduced in 1971 when packed columns were widely used.[64] The basic instrument has undergone considerable refinement over the years but its basic design has changed little.[65,66] With the introduction of reliable capillary columns, packed columns are being phased out.[67–72] MS is increasingly used as an additional tool. Figure 7 shows the outcome of a typical two-dimensional separation.[73] A mass spectrometer was able to deconvolute overlapping peaks. The analysis of highly volatile materials, which has been traditionally done by gas solid chromatography[74] on packed columns, can now easily be conducted on the new generation of porous layer open tubular (PLOT) type capillary columns.[75,76]

2-D GC is also very useful in geochemistry and oil exploration.[76] The analysis of alkylnaphthalenes in crude oil is a good example to illustrate the value of 2-D GC as an indispensable tool. Alkylnaphthalenes are important indicators of geochemical parameters such as the thermal history (maturity) of sedimentary organic matter.[77] The ratio of alkylnaphthalene isomers and other fused aromatic hydrocarbons is an important indicator. These

Chromatograms A (column 100 m × 0.25 mm × 1.2 µm, 5% phenyl 95% methyl polysiloxane) and B (column 25 m × 0.32 mm × 1.0 µm, free fatty acid phase) correspond to primary and secondary separations respectively. (Reproduced by permission from Hendrickx and Ramaekers.[73])

substances cannot be determined by MS because the mass spectra of the isomers are virtually identical. Only 2-D GC can achieve complete resolution.[78,79] Recently, there have been some exciting developments in comprehensive 2-D GC where some peak overlap can be accommodated without the use of valves or other switching devices. Details will be provided in a later paragraph.

The second area where 2-D GC has made a major impact is in the analysis of persistent organohalogens in the environment. The major culprits are chlorinated biphenyls, toxaphenes, dioxins, furans and some pesticides. In many cases, one has to deal with mixtures of isomers in complex matrices. The compounds are usually present at very low levels and detection by selective detectors, in particular the electron capture detector, is necessary. Analysis requires speciation, i.e. the composition of individual isomers must be determined because toxicity and biodegradation between congeners may vary by orders of magnitude. Polychlorinated biphenyls (PCBs) may contain up to 209 distinctive chlorine substituted biphenyl structures.[80] Much effort has been devoted to finding a selective stationary phase capable of resolving the majority of the 150 congeners that may be present in significant quantities.[81–83] A perfect phase has not been found. The sample is simply too complex. 2-D GC, however, can solve the problem.[84,85]

The analysis of PCBs which display axial chirality in their nonplanar conformations is an interesting and challenging problem. It is obvious that the atropisomers must be resolved on a stationary phase with chiral selectivity. Modified cyclodextrins are particularly useful for this purpose.[86] The typical two-dimensional gas chromatograph contains an apolar primary column and a chiral secondary column. Data from environmental

Figure 8 Influence of width of heartcut on the number of compounds isolated from a mixture of polychlorinated dioxins and furans. (Reproduced by permission from Schomburg et al.[90])

samples show that there are indeed differences in the biodegradation of different atropisomers.[87,88] The analysis of toxaphenes which are composed of borane and camphene derivatives provides similar challenges. 2-D GC is amenable to the determination of the various isomers.[89] The determination of chlorinated dioxins and benzofurans is perhaps one of the best known applications of 2-D GC. These classes include some of the most toxic substances ever recorded. Figure 8 shows an application from Schomburg's laboratory dating to the mid-1980s.[90] It is apparent that the width of the window selected for heartcutting has a major influence on the outcome of the analysis. The example shows that the heartcut containing the substance of interest, the 2,3,4,8-congener, must be chosen with precision. Photodegradation studies also rely on high resolution because the fate of individual congeners must be followed to establish correlations between structure and photodegradation rates.[91] High-resolution MS and multisector MS are useful alternatives for dioxin analysis but this technology comes at considerable cost.[92,93]

Pesticide analysis is another important area of analysis where 2-D GC is useful. The trade in foods between different countries requires the routine monitoring of samples for any of the 300 compounds that have been introduced. Most pesticides contain a combination of halogen, nitrogen, phosphorus and sulfur and are thus amenable to selective detection. A combination of electron capture detector, flame photometric detector and nitrogen/phosphorus detector is often used. Identification is usually based on a combination of retention time and detector response ratios.[94] MS is also useful.[95] In critical cases, 2-D GC has to be used in conjunction with selective detectors.[96]

The third area where 2-D GC is widely used is in the analysis of flavors and fragrances. The human nose is a very selective detector that requires a pure substance for organoleptic evaluation. Odor thresholds vary by orders of magnitude. Enrichment may thus become necessary.[97–99] The analysis of essential oils is of considerable interest.[100–102] In practice it is often also necessary to determine the source of ''off-flavors'' in a product that has been rejected by the consumer. Quite often, the substance(s) responsible for the objectionable flavor or taste is present in minute concentration(s) and 2-D GC is the only workable solution.[30] Figure 9 presents an application of this type.[104] The defective coffee sample produced a 10-fold increase of one component. It should be noted that the primary column was intentionally overloaded to provide an adequate amount for mass spectral identification.

Many compounds produced in nature are optically active. The determination of enantiomeric ratios is important.[104–107] It is routinely carried out for a variety of fruits and other natural products.[108–110] Enantioselective 2-D GC is a powerful tool to detect adulteration in foods.[111] Nature usually produces one of the enantiomers in excess whereas synthetic products are racemates. The origin specific analysis of flavors is also possible. Under conditions of identical metabolic pathways, isotope ratios should be indicators of a specific environment. The measurement of carbon-12 to carbon-13 ratios is particularly useful. Isotope ratios provide conclusive evidence. 2-D GC can be combined with on-line isotope MS in the authentication of foods.[31,112,113] The measurement of isotopes requires high precision. Data from isotope measurements are increasingly integrated in many areas where fingerprint-type comparisons are necessary.[114] Regardless of the problem at hand, analysis
